

Diagnostic strategies in rheumatology

Ori Elkayam, Ragnar Gunnarsson and Marianne Angelshaug

A previous version was co-authored by José da Silva, Michelle Hui, Mike Doherty and Uri Arad

GLOBAL LEARNING OBJECTIVES

- Differentiate the main patterns of rheumatic diseases.
- Generate short representations of clinical cases
- Use these representations as guides for a structured approach to questioning and physical examination of the patient and as a framework for final diagnosis

SPECIFIC LEARNING OUTCOMES

- Recognise the importance of case representations, summaries and clinical patterns.
- Differentiate the main patterns of rheumatic diseases based on appropriate questioning and physical examination
- Generate short summaries of clinical cases.
- Use the clinical patterns to guide questioning and reasoning by a two-step approach to diagnosis.
- Differentiate inflammatory arthritis from osteoarthritis
- Recognise atypical osteoarthritis
- Characterise the most common patterns of arthritis and their differential diagnosis
- Recognise axial spondyloarthritis and the different aspects of spondyloarthritis
- Differentiate causes of regional pain
- Recognise fibromyalgia
- Differentiate the most common connective tissue diseases and vasculitis.

1 Basis of diagnostic reasoning

Educational research has shown that the main difference in clinical diagnosis between a novice and an expert clinician lies not mainly in knowledge, but in pattern recognition of the various symptoms, signs and clinical information. This is based on the ability of the expert to shortcut the pathways of clinical reasoning, by recognising patterns and follow trains of thought, through summarised representations of the cases. The expert follows a map, the novice is building one.

Research suggests that expert clinicians have their clinical knowledge organised around 'patterns' or 'illness scripts' that are strongly connected to summary problem representations (Elstein, 2002*; Eva, 2005*). This non-analytical reasoning, guided by scripts, concepts and representations, is an essential component of expertise in diagnosis.

We can think of no better way to convey these concepts than by using Judith Bowen's paper on clinical reasoning published in the New England Journal of Medicine (Bowen, 2006*).

1.1 Patient history

'My knee hurt me so much last night, I woke up from sleep. It was fine when I went to bed. Now it's swollen. It's the worst pain I've ever had. I've had problems like this before in the same knee, once 9 months ago and once 2 years ago. It doesn't bother me between times.'

1.2 Novice resident's presentation

'My next patient is a 54-year-old white man with knee pain. It started last night. He does not report any trauma. On examination, his vital signs are normal. His knee is swollen, red and tender to touch. It hurts him a lot when I test his range of motion. He's had this problem twice before.'

1.3 Expert resident's presentation

'My next patient is a 54-year-old white male with a sudden onset of pain in his right knee that awakened him from sleep. He does not report any trauma and was essentially asymptomatic when he went to bed. He had two episodes of similar, severe pain 9 months and 2 years ago. He is pain-free between episodes. He is afebrile today. His knee is swollen, tender to touch and erythematous.'

Consider the main differences between the two presentations.

As noted by Bowen, the novice resident transformed the patient's story a little but without any particular structure. Key elements of the clinical diagnostic reasoning process are not apparent or structured.

The expert resident transformed the patient's story into a meaningful clinical problem. This can be designated as the 'problem representation' and is an important early step of the diagnostic reasoning process. This first representation guided his choice of additional questions and helped focus his clinical examination. The patient's words are translated into abstract, clinically relevant, terms. 'Last night' becomes 'acute onset', 'I've had this problem before' becomes 'recurrent'. The expert resident presented a succinct summary of findings, highlighting the defining features of the condition and the features that helped discrimination from alternative diagnoses. His description, made into one sentence, might have been this: 'Acute recurrent monoarthritis in an otherwise healthy middle-aged man'. Adequacy and precision of language are absolutely crucial for the efficacy of the process.

The summary description, which is a representation of the problem, helps to elicit the relevant information from memory and guides the subsequent diagnostic investigation. Inability to produce appropriate problem summaries and representations will result in the exploration of multiple diagnostic hypotheses. A wrong summary will lead to a wrong diagnosis.

For this reason, the reader is strongly encouraged to exercise his/her ability to scrutinise and summarise information and checking for its validity.

1.4 The two-step approach to diagnosis

As clinicians we all follow 'a map', a route of non-analytical clinical reasoning. It is important that this process is based on evidence and solid experience. Although experience is considered indispensable for designing your own 'clinical map', this chapter attempts to offer an example to assist the reader with this process.

We propose a 'two-step approach to diagnosis' (da Silva and Woolf, 2010*). The first step aims to define the generic type of pathology, or to set a main pattern. The second step is a more detailed investigation, which is adapted to each pattern and aims to differentiate between potential causes of that pattern, thus making a final differential diagnosis.

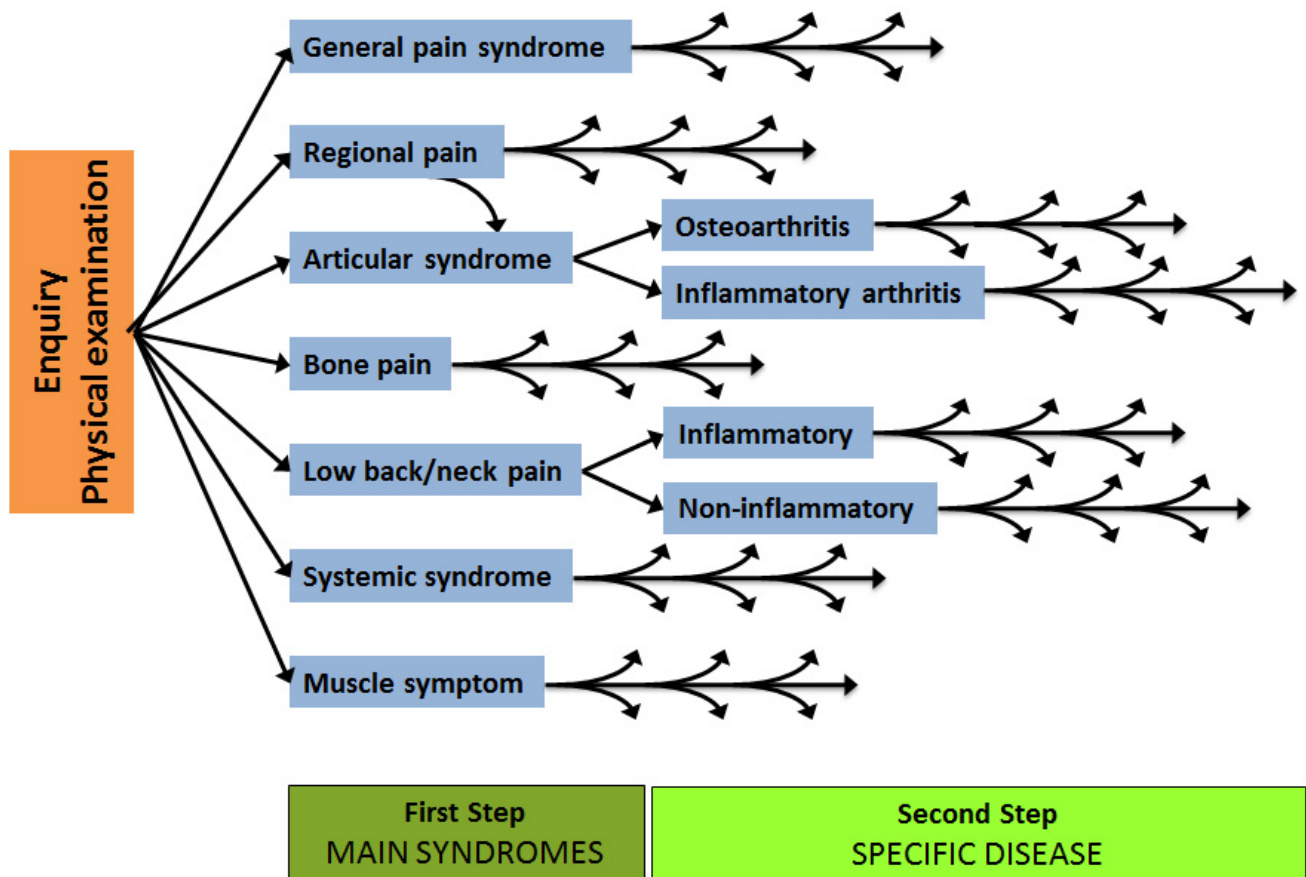

This approach allows us to identify precisely defining characteristics of each main pattern and the most important clues to differentiate between similar conditions and evaluate their severity. The main defining characteristics should guide and focus our strategic questioning and examination. The clinician should be as precise and detailed as possible in reasoning and decision-making while trying to be economical and fast in dismissing 'background noise'.

2 Main patterns

The aim of the first step is to establish the main pattern which is most representative of our patient's clinical picture (pattern recognition). Some of the main patterns are proposed below.

Figure 1 presents a short list of the nine main patterns we propose as a way of organising the first step of the diagnosis. In the following text we will explore the core characteristics of each pattern and its differentiation from others. We will leave the final steps of the clinical diagnostic pathway to the individual chapters dealing with specific conditions.

Figure 1 Main rheumatological patterns. (Reproduced and revised with permission from da Silva, *Reumatologia Prática*, 1st edn. Coimbra, Portugal: Diagnosteo Publishers, 2004.)

It is important to keep in mind that individual patterns are not mutually exclusive. The presence of one pattern does not exclude another. Rheumatic diseases are extremely variable in their presentation: different patterns may be suggested in consecutive patients with the same disease. Seronegative spondyloarthropathies, for example, may present with oligoarthritis in one case and with pure low back pain in the next. But in some other cases periarticular involvement or polyarthritis will dominate the picture, requiring completely diverse differential diagnostic investigations. Our 'map' must be flexible enough to allow for this. This will allow us to reach the right diagnosis quickly, whatever the dominant presenting symptom.

2.1 Regional pain

Regional pain syndromes are characterised by pain that affects a single musculoskeletal area (e.g., shoulder, hand or knee). In some cases several distinct regions may be simultaneously involved (e.g., polymyalgia

rheumatic, radicular pain). Questioning and examination will allow the distinction of four main origins (table 1):

Table 1 Distinctive features of regional syndromes

	Periarticular pain	Articular pain	Neurogenic pain	Referred pain
Enquiry	Only a few selective movements are painful	All joint movements are painful	Dysaesthetic; aggravated by compression of nerve or movement of the spine	Unrelated to movement; 'visceral' timing; poorly localised, may be improved by rubbing
Pain on motion	Active>passive; selected movements	Active passive; several directions	Normal; if root pain: pain on movement of the affected spine segment	Normal
Range of motion	Active movement may be limited by pain; passive movement: full	May be limited equally for both active and passive movement	Normal	Normal
Resisted active movement	Pain on specific manoeuvres	No effect	No effect	No effect
Local palpation	Tenderness over affected periarticular structure (away from joint line)	Possible tenderness over joint line, crepitus, capsular swelling, effusion, increased heat	Normal	Normal
Neurological examination	Normal	Normal	May be abnormal	Normal

- periarticular pain
- joint pain
- neurogenic pain
- referred pain.

The area affected offers an important clue: periarticular lesions are predominantly the cause of pain in the shoulders and elbows, whereas joints are more commonly the cause of pain in the forefeet and knees. The most common patterns of neurogenic pain are sciatica and carpal tunnel syndrome.

2.1.1 Periarticular pain

Periarticular pain originates in anatomical structures that are involved in joint motion but are located outside the joint capsule. Conditions affecting the capsule produce clinical features that are similar to those of intra-articular conditions.

These structures are often the site of disease, which is usually inflammatory, as a result of repeated local trauma (e.g., intensive use of the hands or shoulder) or as local manifestations of systemic synovial diseases, like rheumatoid arthritis (RA). Inflammation of the tendon and ligament insertion points (enthesopathy or enthesitis) may occur in isolation, such as after trauma, and occasionally may have no apparent cause. On the other hand, recurrent and multiple enthesopathies can be a feature of seronegative spondyloarthropathies.

A periarticular origin is especially suggested by pain that is elicited or worsened by specific movements, that involve or compress the involved structure. Other movements usually are not painful or limited (i.e., selectivity of painful movements). Although the condition might be inflammatory, the rhythm of pain tends to be ‘mechanical’—that is, made worse by movement and relieved by rest without joint stiffness.

Another clue from questioning that suggests involvement of a periarticular structure is pain that is made worse in positions that induce a compression of the structure (e.g., increased pain by lying on the affected shoulder, in rotator cuff tendonitis, or on the affected lateral thigh in trochanteric bursitis).

On clinical examination, patients with periarticular lesions will have more pain on active motion than on passive movement (make sure your patient is relaxed on passive movement to assess this clue properly). Passive movement is not limited in periarticular lesions. This is to be expected as the involved structure remains rested during passive movement. Conversely, patients with joint lesions tend to have pain of similar intensity on both active and passive movement and may show equal limitation of both.

Resisted movements involving the periarticular structure will cause intense pain. Such manoeuvres do not cause aggravation of pain when the problem is purely intra-articular. Palpation directly onto the inflamed periarticular structure will reproduce the patient’s pain, whereas with arthritis tenderness is maximal along the joint line. Swelling, heat and redness are usually not seen, except in acute inflammation of superficial bursae, subcutaneous fascia and skin.

2.1.2 Joint pain

A lesion that affects a single joint will obviously result in a regional pain syndrome. Pain is related to use of the joint but, unlike periarticular lesions, all movements tend to be painful. Physical examination will show pain in all movements, with active and passive movements being similarly affected. Joint movement is often limited due to swelling or structural damage. Resisted movements do not exacerbate the pain (as expected since the

joint is not moved by such manoeuvres). Affected joints are often tender on palpation along the joint margins (figure 2). When coarse crepitus, capsular swelling, effusion and/or deformity are also present, this makes involvement of the joint more obvious. Increased articular warmth also indicates intra-articular inflammation, but caution should be exercised to distinguish extra-articular local inflammation, such as in cellulitis overlying a joint.

Figure 2 *Elbow synovitis is an articular syndrome (note the joint line swelling) as opposed to olecranon bursitis which is a periarticular lesion.*

Joint pain will be further elaborated in section 2.4 (Articular syndrome).

2.1.3 Neurogenic pain

Neurogenic pain is caused by compression or irritation of nerve roots or peripheral nerves. Sciatica, carpal tunnel syndrome and ulnar nerve syndrome are the most common examples.

Neurogenic pain typically associates with uncomfortable sensory disturbance (dysaesthesia) with tingling and/or numbness, and is often described as ‘burning’ or ‘like an electric shock’ affecting the sensory distribution of a particular nerve or root. Pain derived from root lesions may be exacerbated by movement of the affected spine segment or by increasing intrathecal pressure through coughing or straining during defecation (or by Valsalva’s manoeuvre during patient assessment).

In the absence of associated pathology, regional musculoskeletal examination is normal. Guided neurological examination is the key to the diagnosis (e.g., testing sensation, muscle strength, straight leg rising, Tinel’s and Phalen’s tests, tendon reflexes, etc.). Because detailed neurological examination is not routinely performed by many doctors, the diagnosis can be easily missed if the enquiry fails to elicit the clues. It is important to keep in mind that muscle atrophy (as in carpal tunnel syndrome) and loss of pinprick sensation are late features in root lesions and nerve compressions.

2.1.4 Referred pain

Referred pain denotes symptoms felt at a distance from their anatomical origin. Axial and large proximal joints (spine, sacroiliac joints, glenohumeral joints, hips) may cause distal radiation of maximal pain, presenting with pain at some distance from the originating structure. For example, although hip pain is often felt maximally deep in the anterior groin, it may present as knee pain with no proximal discomfort. Distinguishing whether hip or knee movement exacerbates the pain is difficult in the history as many daily activities involve synchronous movement of hips and knees. Two clues may suggest referred pain. First, when asked to point to the site of maximal pain the patient often describes a very wide, ill-defined area around the anterior knee which also involves the distal thigh (unlike knee-originated articular or periarticular pain which is well-defined and smaller in area). Second, the pain may be improved by rubbing the area—unlike locally originated pain which is more often worsened by rubbing over it. Examination can decisively distinguish local and referred pain—isolated hip movement will cause the knee pain, and isolated knee movement will not.

Localised musculoskeletal pain can also be referred from internal viscera. Such pain has an uncharacteristic rhythm, being more affected by the physiology of the viscera than by joint movement, and may be accompanied by other more suggestive symptoms. Local musculoskeletal examination is normal and does not reproduce the patient's pain. Figure 3 shows the most common sites of musculoskeletal pain of visceral origin.

Figure 3 Most common sites and origins of referred pain.

2.2 Generalised pain syndrome

In this syndrome, pain affects different parts of the body diffusely and imprecisely, with little or no focus on joints.

Fibromyalgia accounts for the majority of cases of 'multiple regional pain' or 'chronic widespread pain' syndrome. Patients often use or agree with the expression 'pain all over'. Pain is often migratory and worse after, rather than during, exercise. Exposure to cold and stress are frequently recognised as aggravating factors. Commonly, other symptoms are present such as 'tension' headache (often non-throbbing, lasting hours or days, mainly bifrontal), irritable bowel syndrome, tight chest and anterior chest wall pain, low mood, and poor sleep pattern with non-restoration in the morning.

Patients with fibromyalgia may present with different patterns of dominant symptoms, which can be misleading. It is not uncommon for these patients to be misdiagnosed and treated for a variety of conditions, including RA, ankylosing spondylitis (AS), connective tissue disease, disc herniation, etc. Equally, these patients must be carefully assessed to discount co-morbid joint disease, neurological abnormalities and other possible explanations for some of their complaints. The diagnosis is purely clinical and depends on demonstration of widespread hyperalgesic tender sites (i.e., lowered pain threshold) affecting all four body quadrants.

Nevertheless, experienced clinician will keep in mind the limitations of the existing criteria for fibromyalgia. Other rheumatic and metabolic conditions may involve widespread regional pain, including RA, systemic lupus erythematosus (SLE), Sjögren's syndrome, polymyalgia rheumatica (PMR), AS, polymyositis (PM), hypothyroidism, hypoparathyroidism, polyneuropathy, and debilitating systemic diseases. However, widespread hyperalgesia of naturally occurring tender sites is not a feature of these conditions. Careful questioning and examination together with minimal investigation is usually sufficient to clarify the diagnosis and the presence of any comorbidity.

The presence of fibromyalgia in association with other rheumatic conditions is common and represents some of the most difficult clinical situations in rheumatology.

2.3 Low back and neck pain

Back and neck pain is extremely common in medical practice. Most episodes of back pain resolve within a period of 6 weeks, 90% of them after 3 weeks. Back pain of more than 6 weeks' duration requires further investigation. A vast majority of cases will escape a precise aetiological diagnosis even after meticulous investigation. This is due to the anatomic complexity of the spine, muscles, ligaments, nerves and supporting soft tissues in the area, leading to a multiplicity of potential causes. The contribution of current diagnostic methods to clinical diagnosis is limited. The correlation between even sophisticated imaging and clinical manifestations is poor. Used inappropriately, imaging can therefore complicate the clinical picture.

We know that in the vast majority of cases it will be impossible to make a precise diagnosis and treatment will be guided by general rules of pain management, exercise and risk factor control. Only a small percentage of cases involve a specific aetiology requiring special diagnostic and therapeutic action. In patients younger than 45 years, about 5% of cases of chronic low back pain are due to spondyloarthritis. Features suggestive of inflammatory back pain, such as night pain and improvement of back pain with movement but not at rest, may be indicative of spondyloarthritis. In a very few cases the underlying causes are serious—such as malignancy and infection—and require urgent investigation and specific treatment. Such diagnoses cannot be missed.

The first group, by far the most common in a community setting, is ‘common mechanical’ or ‘non-specific’ back or neck pain. Faced with subjective information and unreliable investigations, the experienced clinician will focus on clinical manifestations, pain intensity and disability, more than aetiology, while keeping a careful vigilance for any clues that may suggest a potentially different or serious cause of symptoms for each individual patient. The recommended strategy for back and neck pain is based on the search and recognition of alarm symptoms and signs that indicate a higher probability for an underlying specific cause. Important points of differentiation from common mechanical pain include: progressive pain, night predominance, lack of relationship to spinal movement, and involvement of the thoracic spine. Table 2 summarises some of the summated features that allow distinction between the main categories of back and neck pain.

Table 2 Examples of typical manifestations of different categories of back pain and important red flags

Manifestations	Causes of low back pain
Asymmetrical non-progressive pain (subacute or insidious onset), affecting limited segments of cervical or lumbar spine, worse on movement, no systemic upset	Common mechanical back and neck pain
Axial pain and stiffness with inflammatory rhythm, affecting multiple segments (often including thoracic segments), symmetrical reduction of multiple spinal movements	Spondylitis
Well-localised, progressive pain, worse at night (unrelated to position in bed), may involve thoracic spine. History of prior neoplasm is an additional warning flag)	Malignancy (predominantly metastases) or infection
Acute or subacute onset severe well-localised pain, worsened by even slight movement, often involves thoracic spine (especially with risk or evidence of osteoporosis, older age)	Osteoporotic fracture
Accompanying neurological manifestations	Neurogenic pain
Visceral symptoms, pain not clearly related to spinal movement	Referred pain

The symptoms of mechanical back and neck pain, are commonly triggered by movement and relieved by rest. In adults, most of these conditions are caused by ‘spondylosis’ (a variable combination of facet joint osteoarthritis (OA), intervertebral disc degeneration and ligamentous strain). In many other cases, particularly in young people, there is no apparent cause for the pain and it is thought to be the result of mild articular

instability and irritation of the nerves and muscle bundles, leading to painful reflex muscle contractions. That is commonly treated conservatively aiming to relieve the pain and restore function. In a few cases, the pain may be neurogenic, inflammatory, infectious, neoplastic or psychogenic in nature. The clues for such special conditions are similar to those described above. The possibility of referred pain, from the heart, lung apex and shoulder, must be kept in mind. Acute lymphadenopathy, thyroiditis and meningitis represent important non-rheumatic causes of neck pain.

2.4 Articular syndrome

Arthropathies—that is, diseases affecting the joints—are at the heart of rheumatology. Final diagnosis will involve identification of a specific disease, evaluation of its activity, accumulated damage, the impact on function and participation in daily activities, and prognosis.

As the first step we have to recognise that this is an articular syndrome. As described above, this is suggested by pain that emerges with virtually all movements of the joint as opposed to selective pain found in periarticular lesions. For peripheral joints, patients can usually locate the pain precisely over the joint(s) affected. Pain from proximal joints, as the glenohumeral, sacroiliac, spinal and hip joints may present in distal joints as a referred pain. On examination, pain has similar intensity with active and passive mobilisation and both can be limited in range, unlike in peri-articular lesions where active and passive findings are discordant. Resisted movement will not affect the pain. Palpation will typically cause pain along the margins of the joint. The presence of crepitus, capsular swelling, effusion and/or deformity further confirms the articular origin.

As the second step, four fundamental features of the articular pattern should be defined:

1. 'Inflammatory' or 'non-inflammatory' in nature of the disorder
2. The temporal pattern of the disorder; especially acute versus chronic duration
3. The spatial pattern: primarily, mono-, oligo- or polyarticular arthritis and the presence of axial involvement
4. The existence of extra-articular and/or systemic manifestations.

The most important goal is to differentiate the features of joint damage, predominantly caused by OA, from those of inflammatory joint disease although in some cases a joint may synchronously be inflamed and damaged. Enquiry and physical examination are critical in this respect.

Joint damage/OA is typically associated with 'mechanical' or 'usage-related' pain—pain that increases with repeated use of the joint, which is relieved by rest, and which is often worst towards the end of the day. Patients may describe pain that increases again after resting and this may be accompanied by 'gelling', stiffness that subsides after just a few minutes. Early morning stiffness associated with OA is usually relatively brief, and is 'worn off' in well under half an hour. Symptoms of OA often fluctuate with 'good weeks' and 'bad

weeks' and change only slowly with time. Although OA signs may be detected in many joints on examination (many being asymptomatic), OA usually causes pain in just one or a few joints at any one time.

Conversely, in active inflammatory disease, pain is worst in the morning and is relieved as they get up and start to move their joints. Morning stiffness is often prolonged, lasting for more than 30 min and sometimes for several hours. Stiffness after rest may persist for more than 5 min.

With inflammatory disease sufficient to trigger the acute phase response, the patient may additionally complain of non-specific features such as fatigability, weight loss, night sweats, low mood and irritability, or just say that they 'feel ill'. With inflammatory multi-system diseases, there may also be symptoms and signs of extra-articular manifestations (e.g., anterior uveitis, skin lesions, lung or bowel problems). Such features are not associated with OA, which is purely a condition of the joints, although age-related comorbidities (e.g., obesity, hypertension, depression) may commonly occur in older patients with OA and contribute to their participation restriction.

It is noteworthy that people with OA may suffer 'flares' of pain which may relate to minor inflammation or be biomechanically initiated. During such pain exacerbations patients may have more prolonged morning and activity stiffness. However, inflammation is not a prominent clinical feature and OA does not trigger the acute phase response. Conversely, longstanding but 'inactive' inflammatory arthritis will be associated with 'mechanical' pain reflecting joint damage caused by their inflammatory disease.

Keep in mind that the rhythm of pain can be misleading if applied to non-articular pain. Pain associated with fibromyalgia or carpal tunnel syndrome has 'inflammatory' features, such as morning predominance, although there is no underlying inflammatory process. Conversely, pain from tenosynovitis may have a mechanical rhythm.

Physical examination will support joint damage/OA if there is coarse crepitus, localized joint-line tenderness and/or bony swelling (osteophyte) along the joint margin. Deformity may also be present in later stages of joint damage and OA.

In inflammatory diseases, the synovium becomes inflamed, engorged and eventually hypertrophied, and the volume of synovial fluid increases. This increase in soft tissue and fluid occurs within the limiting confines of the capsule and can increase the pressure within the joint causing pain, stiffness and restriction of movement. A joint with increased intra-articular pressure is most comfortable in the position that minimises the pressure. This position, generally mild to mid flexion, is mainly determined by the tightness of the capsule and is termed the 'loose-pack' position, in which the capsule is normally at its loosest and therefore can accommodate an increase in fluid and soft tissue. Conversely, the positions in which the capsule is naturally tight—the 'tight-pack' positions at the extremes of range of movement—are the positions that are the first to be painful when

synovitis is developing, and the first movements to become restricted. For example, glenohumeral synovitis is most comfortable with the arm adducted and internally rotated as if in a sling, and the patient will naturally adopt this attitude at rest. Conversely, the opposite movements, abduction and external rotation, are the earliest affected and most uncomfortable since these maximise intra-articular pressure.

As the inflamed joint is moved, actively or passively, through its range of movement the pain is minimal or absent in the loose pack position but increases as the joint moves into any of the tight pack positions. This uneven distribution of pain, maximal in all tight pack positions, is called 'universal stress pain'—the most sensitive sign of synovitis, occurring even before there is visible swelling or restricted movement (figure 4). Joint damage is associated with a more even spread of pain throughout the range of movement.

Figure 4 Stress pain and restriction at the wrist—there is no pain in the neutral position, but progressive pain and some restriction as the wrist moves towards full extension or full flexion.

Joint swelling due to soft tissue and fluid, of course, may also become visible and palpable clinically. Because the synovium is limited by the capsule, this swelling takes on a characteristic shape for each peripheral joint. For example, in the knee of a patient lying supine on the couch a small increase in fluid will be visible filling in the medial and lateral concavities or 'dimples' either side of the patella, allowing a 'bulge' sign to be demonstrated as the fluid is pressed transversely from one dimple to the other with the patella stabilised. A large amount of fluid within the knee will cause visible expansion of the suprapatellar pouch above and to either side of the patella, allowing demonstration of the 'balloon sign' (fluctuance). At the finger interphalangeal joints, synovium and fluid expands along the line of least resistance, appearing first as two rounded posterolateral swellings either side of the extensor tendon.

Joint inflammation may also cause increased warmth palpable over the capsular contour. Overlying redness implies an element of periarticular inflammation and this can occur with septic arthritis, gout, acute seronegative arthritis (mainly reactive and psoriatic) and some less common conditions such as palindromic rheumatism. However, even septic arthritis can be present without noticeable redness of the overlying skin, and erythema is not a feature of relatively deep joints such as the hip or shoulder. The summated features that allow distinction between joint damage and joint inflammation are shown in table 3.

Table 3 Differences between inflamed and damaged joints

	Inflamed joint	Damaged joint
Early morning stiffness	Prolonged	Brief
Inactivity stiffness	Prolonged	Brief
Increased warmth	+	–
Stress pain	Yes	No
Capsular soft tissue swelling	+	–
Effusion	+++	+ /–
Coarse crepitus	–	+++
Erythema	+ /–	–
Malalignment/deformity	–	+ /–
Instability	–	+ /–

Of course, the age of the patient, the mode of onset and distribution of affected joints, and the duration of symptoms will also influence our differential diagnosis of OA and inflammatory arthropathies. Joint conditions before the age of 40 years are likely to be inflammatory if not traumatic. Inflammatory arthritis will usually establish itself in a matter of days to weeks or months, whereas patients with OA tend to present to doctors only after years of variable but very slowly increasing pain. An acute monoarthritis on the other hand is a medical urgency and differential diagnosis mainly includes septic arthritis, crystal deposition arthritis, haemarthrosis and trauma (e.g., intra-articular fracture).

2.4.1 Patterns of inflammatory joint disease

We suggest that you always try to represent your patient's condition with as few words as possible, making a 'problem representation' in one sentence—for example, 'asymmetrical oligoarthritis, with inflammatory back pain' or 'acute arthritis with fever and rash'. This will make the final diagnosis a lot easier and reliable. Below, we describe the most common patterns we use in practice (box 1). Be critical of them, as you may find that other patterns work better for you.

Box 1 Characterisation of arthritis

- Number of joints affected
 - Monoarthritis: one single joint affected
 - Oligoarthritis: 2–4 joints affected
 - Polyarthritis: >4 joints affected
- Acute versus chronic
 - Acute: onset in hours or days
 - Sub-acute: up to 6 weeks
 - Chronic: onset over weeks (more than 6 weeks) or months
- Additive versus migratory
 - Additive: the affected joints are added progressively
 - Migratory: the inflammatory process flits from one joint to another
- Persistent versus recurrent
 - Persistent: once it has set, the arthritis persists over time (persistent ≥ 6 weeks)
 - Recurrent: episodes or crises of arthritis separated by symptom-free intervals.
- Predominantly proximal versus predominantly distal
 - Proximal: arthritis mainly affects large joints—that is, proximal to the wrist or ankle and the spine
 - Distal: the arthritis mainly affects the small joints of the hands and feet, with or without the wrist and ankle
 - Large and small joints affected—there is a mixture of joint sizes
- Symmetrical versus asymmetrical
 - Symmetrical: affects approximately the same joint groups on each side of the body
 - Asymmetrical: there is no clear relationship between the joints affected on either side of the body
- With or without inflammatory low back pain
- With or without systemic manifestations

2.4.1.1 Monoarthritis

It is useful to separate acute (onset over hours or days) from chronic monoarthritis.

2.4.1.1.1 Acute monoarthritis

The most common cause of acute inflammatory monoarthritis is crystal synovitis, although septic arthritis should always be considered because it is rapidly destructive and can be life threatening if treatment is delayed. Furthermore, crystals and sepsis can coexist in the same joint.

Crystal synovitis has the following characteristics:

- rapid onset of pain and swelling—at its worst within 6–24 h
- severe pain—often described as ‘worst ever’
- marked tenderness—often unable to bear clothes or bed sheets touching the overlying skin
- often florid synovitis with a tense effusion, adjacent soft tissue swelling and overlying erythema
- the episode is self-limiting, even without treatment, over a few days or a few weeks.

Gout is the most common cause of crystal synovitis. The first episodes often start at night and involve the first metatarsophalangeal joint, although any extremity joint (i.e., hand/wrist joints, elbows, knees, hindfoot,

midfoot, forefoot) may be involved. The attack may develop apparently spontaneously, but recognised provoking factors include local trauma to the joint and intercurrent illness or surgery. Systemic symptoms such as fever and malaise may be present.

Initial episodes of gout almost always follow a monoarticular recurrent pattern with symptom-free intervals, predominantly in the lower limbs. With time, intervals become shorter, the upper limbs also become involved, and more than one joint can be affected in each episode, occasionally leading to a polyarticular pattern.

Acute calcium pyrophosphate (CPP) crystal arthritis ('pseudo gout') presents a similar clinical picture but is mainly restricted to patients over the age of 60 years. It particularly targets the knee. Other common sites are the wrist, shoulder and ankle, although almost any joint can be affected. While a confident diagnosis of crystal synovitis may be made from the clinical characteristics, definitive diagnosis requires demonstration of sodium urate or CPP crystals in aspirated synovial fluid.

The classical presentation of septic arthritis involves the acute or subacute onset of pain, swelling and sometimes erythema in a single joint. Unlike crystal synovitis, symptoms and signs are progressive from day to day and do not plateau in the first 24 h. Systemic symptoms such as fever and malaise may be present. Note, however, that the onset may be more prolonged and inflammatory signs may be relatively mild. RA and immunocompromised status (e.g., diabetes) are risk factors, and sepsis should always be considered in a patient with RA who reports a 'flare' in just one or two adjacent joints. If the diagnosis is strongly suspected, the patient requires immediate admission and treatment for sepsis pending the results of synovial fluid and blood cultures—it is a medical emergency.

Other causes of acute monoarthritis include post-traumatic synovitis, palindromic rheumatism, reactive arthritis, psoriatic arthritis, and bacterial endocarditis. Chronic regional pain syndrome, also known as reflex sympathetic dystrophy, can pose a diagnostic challenge, but mainly involves a region rather than a single joint.

2.4.1.1.2 Chronic monoarthritis

Monoarthritis can have an indolent course, lasting from weeks to months. The main possible causes of chronic inflammatory monoarthritis include infection (*Brucella*, mycobacterium, borreliosis, others), monoarticular presentation of oligo- or polyarthritis (juvenile idiopathic arthritis, reactive arthritis, seronegative spondyloarthropathy), and a foreign body (e.g., plant thorns). Differential diagnosis must incorporate causes of non-inflammatory arthropathy, such as OA, recurrent hydarthrosis, osteonecrosis, chronic regional pain syndrome, neuropathic (Charcot's) joints and tumours, including pigmented villonodular synovitis.

The aetiological diagnosis of chronic monoarthritis usually requires a synovial biopsy with pathological and bacteriological examination and in selective cases PCR technique. In a large number of cases, no specific cause can be identified.

2.4.1.2 Chronic symmetrical additive peripheral polyarthritis

This pattern describes joint inflammation involving, simultaneously, five or more joints (polyarthritis), for more than 6 weeks (chronic). Small joints of the hands and feet are predominantly affected, with or without the wrist, ankle and knee (peripheral), and approximately the same joints are involved on each side of the body (symmetrical). The affected joints have been added progressively (additive) over a relatively short time period (several months). There should be no inflammatory low back pain.

The most common cause for this pattern (figure 5) is RA. Onset of especially aggressive disease may be accompanied by constitutional features such as fever and lymphadenopathy. This could suggest a 'systemic syndrome', but articular manifestations dominate the clinical picture in the vast majority of patients. Other systemic manifestations may occur, but they are usually milder than the arthritis and tend to occur later in the course of disease.

Figure 5 *Chronic inflammatory polyarthritis, symmetrical, small and large joints, upper and lower limbs – the typical presentation of rheumatoid arthritis.*

This pattern of arthritis is common to other rheumatic conditions, especially other connective tissue diseases, such as SLE, primary Sjögren's syndrome, polymyositis (PM) and mixed connective tissue disease (MCTD). Psoriatic arthritis can also present with this pattern, although it tends to be more asymmetrical and involve either the distal interphalangeal or the sacroiliac joints. OA with CPP crystal deposition (CPPD) deserves consideration, especially in older patients. A pre-existing pattern of generalised OA with recurrent inflammatory episodes may suggest this condition. Chronic polyarticular gout may have a similar pattern of distribution. However, almost invariably this is preceded by a period of recurrent monoarthritis. Viral arthritis, such as is associated with parvovirus B19, HIV and hepatitis, may follow a similar pattern, but tends to have a more acute onset than RA or the connective tissue diseases.

The clinical contribution to differential diagnosis relies on careful evaluation of extra-articular manifestation. Further investigations may be useful.

2.4.1.3 Chronic asymmetrical oligo/polyarthritis

This describes an asymmetrical arthritis present for more than 6 weeks (chronic), affecting two or more proximal or distal joints (oligo/polyarthritis). Dactylitis, enthesitis or involvement of distal interphalangeal joints is a common but not mandatory feature. The combination of synovitis with adjacent periarticular inflammation (one example being dactylitis) is strongly suggestive of seronegative spondyloarthropathy.

Psoriatic arthritis is the most common cause of this pattern (figure 6). A personal or family history of psoriasis will provide support for this diagnosis. When the arthritis is limited to proximal and distal interphalangeal joints, hand OA needs to be considered as an alternative diagnosis. Although this usually has a slow development, it may evolve with acute inflammatory flares of these joints. Chronic sarcoid arthropathy may evolve with a similar pattern—the inflamed joint tends to show a nodular asymmetrical aspect as opposed to the spindle shape of psoriatic synovitis.

Other seronegative spondyloarthropathies, such as AS, may also cause this pattern of arthritis, mainly asymmetric oligoarthritis. Inflammatory back pain is expected in this condition, but may not be obvious. Reactive arthritis or arthritis associated with inflammatory bowel disease may show this pattern, but when distal joints are affected they usually adopt a symmetrical distribution.

Other causes include incipient RA, juvenile idiopathic arthritis, polyarticular gout, OA with CPPD, and Behçet's disease. Again, careful enquiry about axial and extra-articular manifestations including enthesopathy and uveitis may provide critical clues to the diagnosis.

Figure 6 Chronic inflammatory polyarthritis, asymmetrical, with synovitis plus adjacent periarticular inflammation (e.g., dactylitis)—a characteristic distribution for seronegative spondyloarthropathy.

2.4.1.4 Proximal oligoarthritis

Patients may present with inflammatory arthritis involving predominantly proximal joints. The most common causes are the seronegative spondyloarthropathies. Complete questioning and physical examination is important for differential diagnosis. The presence of inflammatory low back pain, a personal or family history of psoriasis, inflammatory bowel disease, AS, uveitis, and the occurrence of any infectious disease (infectious diarrhoea, urinary tract infection) in the weeks preceding arthritis must be explored in the enquiry.

Other causes of proximal oligoarthritis include Behçet's disease, juvenile idiopathic arthritis and incipient RA. It is not uncommon for arthritis with this pattern to defy formal classification and is better described as unclassified oligoarthritis.

Polymyalgia rheumatica is in the differential diagnosis of proximal oligoarthritis. The patient is typically an elderly person, presenting with pain and stiffness in the neck, shoulders and hip girdle due to inflammation that mainly affects the peri-articular structures (tenosynovial sheaths, bursae). Peripheral joints can be involved. Some extra-articular manifestations must be explored in questioning. Malaise, fever, fatigue, anorexia and weight loss are common features. Jaw claudication, temporal headaches and loss of vision suggest concurrent temporal arteritis.

2.4.1.5 Acute oligoarthritis or polyarthritis: febrile arthritis and arthritis with manifestations of the skin and mucous membranes

This is characterised by a rapid onset of oligo- or polyarthritis, often associated with a recent infection, fever or changes in skin and mucous membranes.

This pattern suggests the possibility of reactive arthritis. In these cases, the patient is most often a young adult man. The enquiry should explore the occurrence of a significant infection within the 2–3 weeks before the arthritis. There is a wide variety of potential causal agents, but most frequently this will be gastrointestinal, genitourinary or upper respiratory infection. Reactive arthritis is often associated with manifestations in the skin (e.g., rash, erythema, keratoderma blenorrhagica) and mucosae (conjunctivitis, urethritis, oral or genital ulceration, circinate balanitis).

The pattern of articular involvement varies. Proximal oligoarthritis is the most common, but in cases of post-streptococcal reactive arthritis or post-viral arthritis, such as parvovirus, HIV, hepatitis C and B and tropical viruses, it is often polyarticular and symmetrical.

Still's disease (in adults or children) is characterised by an acute or subacute onset of arthritis, associated with fever, evanescent skin rash, weight loss, lymphadenopathy and/or splenomegaly. SLE, dermatomyositis (DM), Behçet's disease and, occasionally, RA may present with similar features and should be considered in the differential diagnosis.

Löfgren's syndrome is a type of acute sarcoidosis that is most commonly accompanied by bilateral ankle arteritis and fever, erythema nodosum especially of the legs. A chest radiography will commonly reveal bilateral hilar lymphadenopathy.

2.4.1.6 Periodic arthritis with fever

Recurrent episodes of arthritis with fever point to the diagnosis of rare hereditary disorders with a common phenotype of lifelong, recurrent inflammatory episodes, characterised by inflammatory symptoms such as fever, abdominal pain, diarrhoea, rash, or arthralgia. Between the fever episodes, patients with most of these syndromes generally feel healthy and function normally. These syndromes include familial Mediterranean

fever, cryopyrin-associated periodic syndrome (CAPS) and others, usually starting in childhood although late onset has been described.

2.4.1.7 Polyarthrititis with systemic manifestations

This is characterised by polyarthrititis with clear manifestations or strong suggestion of compatible systemic involvement.

SLE is the most common cause but other connective tissue diseases must be considered in the face of this pattern of involvement.

Reactive arthritis and viral arthritis could present with polyarticular involvement and are associated with systemic manifestations, although these are usually of a different nature. Still's disease may deserve consideration when this pattern is present.

2.4.2 Inflammatory back pain

Inflammatory back pain is axial and symmetrical, affects multiple segments, is not relieved by rest but rather by movement, and is associated with prolonged morning stiffness. Low back pain may radiate to the buttocks and patients may describe alternating buttock pain.

Inflammatory back pain is a typical manifestation of seronegative spondyloarthropathies: non-radiographic axial spondyloarthritis, AS, psoriatic arthritis, reactive arthritis, and spondylitis of inflammatory bowel disease. Other conditions to consider are Behçet's disease and infectious or aseptic discitis.

In seronegative spondyloarthropathy, the spine is very often affected and may or may not be accompanied by involvement of the peripheral joints. When the condition is strictly limited to the spine, non-radiographic axial spondyloarthritis or AS becomes the most probable diagnosis. If peripheral joints are also affected, the pattern of distribution and the associated manifestations are the key to the final diagnosis. Psoriasis, inflammatory bowel disease, uveitis, urethritis, conjunctivitis, venous and arterial thrombosis, and mucosal ulcerations must be explored in the history and examination.

2.4.3 Patterns of OA

OA typically develops in middle-aged or elderly people and in some joints, such as the hip or knee, symptoms may get slowly worse with time, whereas in others, such as finger interphalangeal joints, symptoms may improve. Common target sites for involvement are shown in figure 7. However, although joints such as the shoulder and elbow are not target sites for OA, the most common cause of arthritis in these joints is OA simply because of the very high prevalence of OA compared to other arthropathies.

Figure 7 Target sites for osteoarthritis are shown on the left in black; joints that are relatively spared are shown in grey on the right.

Nodal generalised OA is characterised by multiple Heberden's and Bouchard's nodes and involvement of other common target sites for OA. It predominates in middle-aged and older women and there is often a family history.

'Atypical' OA is suggested by uncommon characteristics, such as onset at a young age or an unusual joint distribution, in a patient who has usage-related pain and signs of joint damage, without inflammation. Such features should alert the clinician of the possibility of an underlying predisposing condition. Young-onset mono-articular OA (<50 years old) is most commonly a result of previous major joint injury (e.g., subchondral fracture, torn meniscus, cruciate ligament tear). However, young-onset pauci- or polyarticular arthritis that clinically, and even radiologically, appears as OA should lead to consideration of specific conditions that predispose to joint damage (box 2). Most of these have their own additional clues on enquiry and physical examination.

Box 2 Causes of ‘atypical’ osteoarthritis with young onset or atypical distribution**Mainly monoarticular:**

- Prior trauma or injury (e.g., fracture involving the articular surface, meniscectomy, instability, osteochondritis dissecans)

Mainly oligo- or polyarticular:

- Spondylo-epiphyseal and epiphyseal dysplasia (may have short stature and family history)
- Pre-existing arthritis (e.g., prior juvenile idiopathic arthritis, septic arthritis)
- Haemochromatosis (often targets hip, wrist, metacarpophalangeal joints)
- Neuropathic joint (hindfoot—diabetes; shoulder, elbow, wrist—syringomyelia; knee, spine—syphilis)
- Osteonecrosis (mainly hip, shoulder, knee, elbow)
- Endemic osteochondropathy (e.g., Kashin-Beck disease, Mselini disease)

OA itself is a risk factor for crystal deposition (CPP, basic calcium phosphates and sodium urate). Therefore, if a patient with apparent OA has an additional superimposed inflammatory component, especially with ‘flares’ of clinically overt inflammation, examination of a synovial fluid aspirate, particularly for CPP and urate, is warranted.

2.5 Bone pain conditions

Bone pain can have different presentations. One form that is important to identify is pain characterised by deep, diffuse, continuous pain, unrelated to movement and not typically confined to joints. Frequently, pain will be worse at night and disturb the patient’s sleep. These features should raise consideration of bone tumours, metabolic bone diseases or inflammation of the periosteum. Metastatic tumours are the most common neoplasms of bone, and bone is the third most common site of metastasis after the lung and liver. Pain due to a metastatic lesion may be the first symptom of the underlying malignancy. Common sites affected include the spine, the pelvis and the proximal segments of the limbs. The local examination is usually normal and does not reproduce the patient’s pain.

Another form of bone pain results from fracture. This pain may be more acute or subacute in onset, is very well localised without any radiation, and is often worse on minimal movement. Risk factors for osteoporosis and fractures include postmenopausal status, early menopause, late menarche, low body mass index (BMI), sedentary lifestyle, low dietary dairy intake, and family history of osteoporosis or fracture. Secondary causes include malabsorption, hypogonadism, hyperthyroidism, hyperparathyroidism, excess alcohol use, and prolonged glucocorticoid use.

2.6 Muscle symptoms

Myalgia is a frequent symptom of viral infections, but is also commonly associated with systemic diseases such as lupus, vasculitis and PMR. These may cause pain and muscle tenderness, but usually not weakness. However, primary muscle disease is most commonly reflected by proximal weakness and muscular atrophy.

Myopathic patients may have difficulty going up and down stairs, getting up from a low chair or combing their hair, but their handshake is firm and they can walk on tiptoe. Examination may show decreased proximal muscular power and muscle tenderness. Muscle atrophy is a later and inconsistent finding.

PM, DM and inclusion body myositis (IBM) are the most typical causes of this pattern. Arthralgia and low grade arthritis may also occur, especially when inflammation of muscle occurs as part of a connective tissue disease, such as systemic sclerosis or MCTD. Systemic complaints such as low grade fever, fatigue, weight loss and skin rashes are often present.

The differential diagnosis of adult PM/DM must include a broad array of conditions capable of affecting skeletal muscle. Hypothyroidism, sarcoidosis, and metabolic myopathies must be considered in this clinical context, as the myopathy associated with these conditions may dominate the clinical presentation. Muscle pain and stiffness of the proximal limb girdles, characteristic of PMR, may be interpreted as myopathy, but with PMR muscle weakness is not a feature.

Rheumatologists should also give special attention to commonly used drugs which can cause neuromuscular complications, including glucocorticoids, hydroxychloroquine, colchicine, cyclosporine, statins and fibrates among several others.

Non-inflammatory myopathies must also be considered and they include an enormous variety of neurological conditions, such as spinal muscle atrophies, myasthenia gravis, myotonic diseases, congenital myopathies and storage diseases.

Generalised muscle pain with 'tender points' is an integral part of fibromyalgia can lead to a subjective feeling of muscle weakness which in most cases is not confirmed on physical examination.

2.7 Systemic syndrome

Inflammatory joint diseases may be accompanied by extra-articular manifestations. Examining for extra-articular manifestations should be an integral part of the investigation. Commonly, these manifestations occur together with polyarthritis and sometimes they can dominate the clinical picture. The term 'systemic syndrome' is a term used to further explore the diagnosis. Table 4 presents the most common and relevant manifestations.

Table 4 Main systemic manifestations associated with rheumatic diseases

Main systemic manifestations associated with rheumatic diseases	Associated diseases*
<i>Constitutional manifestations</i>	
Fever	RA, SLE, DM/PM, SSc, MCTD, vasculitis, FMF and other periodic fever syndromes
Weight loss, severe fatigue	RA, SLE, DM/PM, SSc, MCTD, vasculitis
<i>Skin manifestations</i>	
Photosensitivity, alopecia	SLE, DM
Sclerodactyly, telangiectasia	SSc, MCTD, overlap syndromes
Heliotrope rash, Gottron's papules	DM
Raynaud's phenomenon	Idiopathic Raynaud's phenomenon, SSc, SLE, MCTD
Psoriasis	Psoriatic arthritis
<i>Mucosal manifestations</i>	
Oral and genital ulcers	SLE, Behçet's disease, Crohn's arthropathy, vasculitis
Dry eyes and mouth	Sjögren's syndrome, rheumatoid arthritis
Serositis	SLE, rheumatoid arthritis, MCTD, FMF
Uveitis	Reactive arthritis, ankylosing spondylitis, Behçet's disease and other vasculitis, sarcoidosis
Scleritis, episcleritis	Vasculitis, relapsing polychondritis
<i>Others</i>	
Arterial or venous thrombosis	Vasculitis, antiphospholipid antibody syndrome, Behçet's disease
Recurrent abortion	Antiphospholipid antibody syndrome
Dysphagia	SSc, MCTD, PM/DM, IBM
Dyspnoea	Several connective tissue diseases
Lower limb oedema, hypertension	SLE
Lymphadenopathy	Several connective tissue diseases
Muscular weakness	PM/DM, IBM, MCTD, SSc myositis, overlap syndromes
Convulsions, psychosis	SLE, CNS vasculitis, antiphospholipid antibody syndrome
Peripheral neuropathy	Vasculitis, primary Sjögren's syndrome, SLE, sarcoidosis, RA
ENT manifestations—sinusitis, otitis media, deafness	Vasculitis
Diarrhoea	IBD related arthropathy

*In approximate descending order of prevalence.

DM, dermatomyositis; ENT, ear, nose and throat; FMF, familial Mediterranean fever; IBD, inflammatory bowel disease; MCTD, mixed connective tissue disease; PM, polymyositis; IBM, inclusion body myositis; SLE, systemic lupus erythematosus; SSc, systemic sclerosis

Connective tissue diseases and vasculitides are the most common causes of systemic syndrome. Their distinction is based on the predominant clinical manifestations of each disease (table 5). The clinician must, however, exercise flexibility here as overlap between different diseases is extremely common.

Table 5 Manifestations associated with the different connective tissue diseases

Manifestations	SLE	Systemic sclerosis	PM/DM	MCTD	Vasculitis
Constitutional symptoms	++	–	+	+	+++
Arthritis	+++	+	+	+++	+
Diffuse swelling of the hands	Rare	++	Rare	++	–
Photosensitivity	+++	+	+++	+	–
Cutaneous sclerosis	–	+++	–	+	–
Calcinosis	–	+++	–	–	–
Erythema	++	–	++	+	–
Vasculitic lesions	+	+	Rare	Rare	+++
Raynaud's phenomenon	+	+++	+	+++	+
Hair loss	++	++	Rare	Rare	Rare
Sicca syndrome	++	++	+	++	–
Uveitis/scleritis/episcleritis	Rare	–	–	–	++
Serositis	++	+	–	++	–
Arterial and venous thrombosis*	+	Rare	Rare	Rare	+++
Miscarriages*	+	Rare	Rare	Rare	Rare
Central nervous system	+	Rare	Rare	Rare	+

Haematological	+++	–	–	++	–
Renal	+++	++†	Rare	+	++
Pulmonary	+	++	+	++	++

The number of ' + ' signs reflects the weight of the manifestation as an argument in favour of a diagnosis.

**In secondary antiphospholipid antibody syndrome.*

†Hypertensive crisis, drop in creatinine clearance.

MCTD, mixed connective tissue disease; PM/DM, polymyositis/dermatomyositis; SLE, systemic lupus erythematosus.

Vasculitis encompasses a large number of conditions with a wide range of manifestations. This is further explored in a dedicated discussion in the EULAR online course (<http://www.eular-onlinecourse.org>).

Still's disease typically presents, in both children and adults, with a systemic syndrome dominated by fever, rash, weight loss and lymphadenopathy and leucocytosis in addition to arthritis. Serositis, pneumonitis, hepatomegaly and myalgia may also be present in a complex multisystem clinical situation demanding differential diagnosis with connective tissues diseases, vasculitis, malignancy and infection, among others.

Occasionally, reactive arthritis may be dominated by extra-articular features, such as uveitis, nephritis, carditis, and gut and eye inflammation. Sarcoidosis should be especially considered in the presence of lymphadenopathy, erythema nodosum, or lung, eye or liver involvement.

Relapsing polychondritis and familial Mediterranean fever may also deserve consideration in the context of a systemic syndrome.

3 The 'optimal' enquiry and examination in rheumatology

Whether we are aware of it or not, we begin our differential diagnosis with our first question and then test out, reinforce or eliminate hypotheses as the enquiry goes on. The ideal enquiry should be 'economical' and critical.

3.1 Focus on relevant concerns

By 'economical' we mean short and focused, but still comprehensive and empathic. Relevant information should be explored, but irrelevant should be discarded.

Irrelevant information creates distraction or 'background noise'. To master this ability requires a clear view of what is the key information and what needs to be taken into account during the diagnostic process or treatment selection. Let us use an example. The sequence of involvement of joints in a polyarthritis makes no difference to the diagnosis: the interpretation of a chronic symmetrical peripheral polyarthritis is the same irrespective of whether the first joints affected are the feet or the hands, the wrists or the metacarpophalangeal joints. This detail is, therefore, irrelevant and should not be explored. We do not need to ask for the rhythm of pain in individual joints involved in polyarthritis.

However, we must do that for an associated back pain. In most cases this will be a comorbid non-specific mechanical back pain with no added significance. However, low back pain with an inflammatory pattern is a crucial clue to the interpretation of peripheral polyarthritis.

There is no absolute measure of the value of any piece of information that can be applied to every clinical setting. Be critical about the importance to any feature. Focus on the most important topics for your reasoning and make your own problem representation in one sentence.

3.2 Assess the validity of information

To make the enquiry work in an optimal way, it is crucial that you critically appraise the validity and the degree of certainty of each piece of information and be aware of the impact on your reasoning.

Your map is made of crossroads where your choice is guided by a signal or symptom. It is important to pay good attention, especially to signs that drive you in a very different direction. If you misread a signal, you are bound to choose the wrong road. Never forget to make an appropriate enquiry of systemic symptoms.

Symptoms and signs are often poorly defined and subjective and you cannot always be sure that you have read them precisely. This is an inherent problem in clinical medicine, but we suggest two methods to try to diminish these risks. One suggestion is that you discuss crucial symptoms with the patient in different ways, using variable expressions until you are certain you have understood the patient exactly. For this purpose, it is useful to summarise your interpretation and negotiate it with the patient.

You should keep an open, critical mind about signals and symptoms that are influential but not very precise. When facing such a problem, explore one direction, assuming the sign is real and reliable, and then explore the alternative directions—that is, different interpretations of that sign.

3.3 Listen to the patient

Dealing with the patient's concerns is the core to the objectives of the clinical encounter. Additionally, patient clues will feed your lateral thinking, open your eyes around 'predetermined' scripts, and keep you from disregarding relevant problems that you had not considered.

Examples are numerous and common: a patient describing pain and stiffness around the shoulders is finally given an opportunity to refer to his or her weight loss; back pain is finally related to a perforated ulcer when we listen to the patient's digestive complaints; unexplained pain is clarified when we allow ourselves to listen to hints of anxiety and distress, etc. Give the patient a couple of minutes at the start of the enquiry. This will help to focus the problem. Make sure that you hear the patient's own story but not formulations from other doctors.

Published reports have shown that specialists in ears, nose and throat interrupt their patients within 2 seconds of the start of an enquiry; there is no reason to believe that rheumatologists are any different. Crucial information may, thus, be lost.

Be vigilant about whether your strategy allows enough room for the patient's expression of all relevant information. Be sure always to end your questioning by asking the patient: 'Is there anything else troubling you that I haven't asked about?'

3.4 Examine properly

Physical examination will play a major role in clarifying the diagnosis. Examination is extremely important to determine the anatomical origin of the pain (articular, periarticular, muscular, neurogenic, etc.) and the nature of the disease (degenerative, inflammatory, entrapment). Once you have finished the enquiry, you will have a

natural tendency to approach the physical examination with a biased tendency to confirm expectations. If, before the examination, you are 'convinced' that your patient has fibromyalgia, you may put slightly more pressure on the tender points, ignore doubtful signs of joint swelling or forget to explore the sacroiliac joints.

Careful musculoskeletal examination can be performed in a short time and can be easily combined with an adequate general examination. Although this examination is not technically demanding, it must be done with appropriate care and detail. Pain on movement of the ankles can be arthritis or Achilles tendonitis, for example; tenderness due to anserine bursitis may be wrongly taken as indicating arthritis; pronator syndrome will never be diagnosed without the proper examination techniques; trochanteric bursitis can closely mimic sciatica, etc.

3.5 Summarise the data

We suggest that you try to define each symptom or syndrome with as few words as possible. Be aware of the exact meaning and implication of each word, on others and on yourself. Once you 'decide' or say that a patient has 'arthritis', you allow yourself and others to exclude muscle pain or periarticular lesions from consideration. Being aware of what it takes to say that a patient has arthritis; you may consider using the word arthralgia, or arthropathy to refer to less defined conditions. This exercise will help you to scrutinize the validity for each piece of data you use. Using specific terms when possible will enhance the precision of your communication with others and of your own reasoning process.

By summarising the data you focus on what is relevant, diminish 'background noise', and enhance the efficiency of your reasoning. Most nuances are not crucial for diagnosis: there is, for example, a certain temperature profile which is more typical of Still's disease, but you should think of this hypothesis in any patient with fever, arthritis and lymphadenopathy. Nuances that are 'really' important should be part of your summarised description, anyway.

In the clinical exploration the doctor must have a split mind: one part is interacting and keeping empathy with the patient, while the other is checking the map, the quality and relevance of signs, and to direct the diagnostic journey.

4 Role of laboratory tests in rheumatology

Laboratory tests have limited usefulness in the diagnosis of most rheumatic conditions. Their influence varies according to the clinical picture and they should be chosen to clarify a clinically supported hypothesis. Ordering a battery of laboratory tests will often introduce information noise and cost rather than clarify the diagnosis.

The ability of a test to classify subjects correctly as having or not having a given disease depends on sensitivity and specificity.

Sensitivity is the proportion of true positives (i.e., true patients) who are correctly identified as such and is, therefore, equal to 1 minus the false-negative rate. Specificity is the proportion of true negatives (i.e., non-patients) who are correctly identified as such and is, therefore, equal to 1 minus the false-positive rate.

Specificity is profoundly affected by the population used to establish it—that is, the number and medical conditions of the control population. For example, the prevalence of rheumatoid factor in the general healthy population increases with age and is associated with a variety of non-rheumatic conditions (such as endocarditis and tuberculosis) and rheumatic diseases such as Sjögren's syndrome and SLE. The calculated specificity in any given study will be increased by exclusion of the confounding conditions from the control group and decreased by the inclusion of older people or patients with SLE. Ideally, we would have accurate numbers reflecting the clinical context of each individual patient, but that is, obviously, impossible.

Taken lightly, sensitivity and specificity can be easily overvalued in practice. The clinician needs to consider the limitations of these numbers. Let us consider, for example, antinuclear antibodies (ANA) and the diagnosis of SLE.

It is certainly remarkable that ANA can be found in over 95% of patients with SLE. A negative ANA test certainly makes the diagnosis of SLE very unlikely. A positive test supports the diagnosis, but the impact will depend on the clinical situation. Positive ANA are also found in about 5% of the general population, with the incidence rising with increasing age. However, SLE is a rare disease, affecting about 1 in 2000 of the population. This makes SLE a relatively rare cause of positive ANA. If all people with musculoskeletal symptoms were 'blindly' screened for ANA (about 20% of the total population), 100 in 2000 of the population would be found to have ANA, while only one would have SLE. Therefore most people with a positive ANA test do not have SLE or any other rheumatic condition. Similar limitations, obviously, apply to other tests.

Adequate weighing up of sensitivity and specificity can be helped by stating to oneself the complementary message: rheumatoid factor is present in 80% of patients with RA (sensitivity), therefore 20% of patients with RA do not have rheumatoid factor.

The impact of test results on the probability of the diagnosis is better supported by consideration of the pre-test probability and the likelihood ratio. A positive test could increase the likelihood of the diagnosis, on the contrary, a negative result could 'rule out' a suspected disease. This and other aspects of weighing up evidence and laboratory results are explored in more depth in another chapter, dedicated to the critical appraisal of evidence.

Summary points

- **Willing or not, nearly all practising clinicians follow trains of thought and use ‘maps’ of clinical reasoning.**
- **Reflect on your practice, take lessons from your own experiences and incorporate them into your own ‘mind map’.**
- **Focus on the typical characteristics of each condition and on the crucial aspects that differentiate it. Give attention to indicators of prognosis, activity and progress.**
- **Never forget the decisive role of enquiry and examination in diagnostic process.**
- **Balance the need to guide your patient through the enquiry and his/her freedom to express their concerns.**
- **Always be critical about the clarity, validity, accuracy, sensitivity and specificity of the clinical and laboratory data you use.**
- **Be aware of the importance of words as ‘guides of thought’ and exercise the use of clinical descriptors that are as accurate and precise as possible.**
- **Make a problem representation in one sentence.**
- **Consider the ‘mind map’ we offer in this chapter as a mere example, waiting to be adapted and continually revised by you, in a search for the map that works best for you and your patients.**

IN-DEPTH DISCUSSION I

Vasculitis: diagnostic strategy

A 45-year-old man is admitted to your department.

His history is:

I'm visiting you because of a rash on my legs which I noticed just yesterday. I have been unwell for about 3 weeks. I have pain all over, and I have also felt sweaty at night and have lost 2 or 3 kg. I don't feel right and am very tired.

Clinical examination and laboratory results show a palpable rash on his legs (See Figure). His blood pressure is 195/100 mmHg, temperature 37.8°C, and diffusely tender muscles. Urine dipstick shows 1+ of protein. Lab reveals mild normocytic and normochromic, anaemia and a CRP of 85 mg/L (normal <5 mg/L).

Try to formulate a one-sentence representation defining the case in abstract terms

The one-sentence representation can be as follows:

A 45-year-old Caucasian male with a systemic syndrome consisting of B-symptoms for 3 weeks and a non-itching palpable purpuric rash suggestive of leukocytoclastic vasculitis. He has hypertension and proteinuria which might point to possible involvement of his kidneys.

Could it be an Infectious disease?

Yes – it could be – the relatively short duration of symptoms and low-grade fever might point to an infectious process such as parvovirus B19, HCV, HBV or SBE. A vasculitic rash and an increased CRP could be a manifestation of these diseases as could kidney involvement. Serological studies and cultures should be performed.

In addition to ruling out infection, how should we classify this cluster of symptoms? Answer: a systemic clinical picture for which the DD includes vasculitis, SLE, PM/DM, MCTD/pSS

Could this patient have a vasculitis? Why?

Yes, the patient might have a vasculitis. He has constitutional symptoms and signs of systemic disease with kidney involvement. The vasculitis rash further strengthens this possibility although it is not mandatory.

DIAGNOSTIC APPROACH

Step one: When to suspect vasculitis?

Vasculitis is an inflammation of blood vessel walls. It is a highly heterogeneous group and can affect vessels of all sizes in any organ. The clinical picture of vasculitis can vary from a benign loco-regionally restricted processes to systemic necrotising vasculitis leading to life-threatening conditions.

The presenting symptoms (Table 1) varies. They include such constitutional symptoms as fatigue, weight loss, night sweats and low grade fever (the B-symptoms) and also more specific symptoms derived from tissue and organ ischemia, such as claudication, angina, stroke, cutaneous ischemia and mesenteric ischemia depending on the vessels involved. Several organs may be affected. Ischemia is especially suggestive when it affects a

young person without atherosclerosis. Also multiple organ dysfunctions in a systemically ill patient should raise the possibility of vasculitis.

You have to suspect vasculitis when a patient presents with:

- Unexplained systemic illness
- Symptoms of organ system ischaemia
- Nephritic syndrome

Table 1. When should we suspect vasculitis? This shows the most common manifestations, remember that most manifestations can be seen in any kind of vasculitis

General clinical feature	Signs or presenting disorders	Type of vasculitis
Constitutional symptoms	Low grade fever, fatigue, malaise, anorexia, weight loss	GCA, GPA, MPA, eGPA, PAN, less commonly other vasculitis.
Polymyalgia rheumatica	Proximal muscle pain with morning stiffness	GCA
Myalgias	Diffuse	PAN , GPA, MPA, eGPA
Non-destructive oligoarthritis	Joint swelling, warmth, painful range of motion, migratory	PAN, MPA, eGPA, GPA, hypersensitive vasculitis
Skin lesions	Livedo reticularis, necrotic lesions, ulcers, nodules, digital tip infarcts	Any medium-vessel vasculitis
	Palpable purpura, urticaria-like	Any small-vessel vasculitis
ENT symptoms	Sinusitis, otitis, hearing loss	GPA, eGPA, MPA
Cranial symptoms	Headache	GCA, TAK, GPA
Multiple mononeuropathy (mononeuritis multiplex)	Injury to two or more separate peripheral nerves (e.g. drop foot, wrist drop)	PAN, eGPA and GPA MPA,

Renal involvement	Renal artery involvement	PAN, TAK
	Glomerulonephritis	MPA, GPA, cryoglobulinaemia, Henoch-Schönlein purpura
Gastrointestinal involvement	Abdominal pain, nausea, diarrhoea, bleeding	GPA, eGPA, PAN, Henoch-Schönlein purpura
Cardiovascular involvement	Hypertension	Any type of vasculitis
Ocular involvement	Visual disturbance	GCA, TAK, GPA
	Scleritis, episcleritis, uveitis	Behçet's disease, GPA
Pulmonary involvement	Asthma	eGPA
	Infiltrates	GPA, eGPA

GPA Granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis); eGPA Eosinophilic granulomatosis with polyangiitis (formerly known as Churg-Strauss syndrome); MPA Microscopic polyangiitis; GCA Giant cell arthritis; TAK Takayasu's arteritis.

In this In-depth discussion, we have now given you the first step of your two step approach to diagnose vasculitis: when to suspect vasculitis.

Now reaching step two you have to be aware that several other conditions can mimic vasculitis or initiate a secondary vasculitis. These conditions need to be considered and excluded before you finally decide on the specific type of primary vasculitis.

Think about diagnostic groups that might mimic vasculitis

Mimics of vasculitis:

- Infections
- Embolic disorders
- Malignancy
- Drugs

Consider diagnostic groups that can cause secondary vasculitis

Conditions that may cause secondary vasculitis

- Infections
- Drugs
- Malignancy
- Connective tissue diseases

These lists pose an important practical dilemma: immediate onset of immunosuppressive treatment might be lifesaving in primary vasculitis – but it could also be fatal in cases of an infectious disease.

A structured diagnostic approach is indispensable.

Step two: The diagnostic strategy

Having considered the possibility of primary vasculitis we suggest you try to answer the following questions in succession:

Is this a condition that could mimic the presentation of vasculitis?

Is this a secondary vasculitis?

How do I confirm the diagnosis of vasculitis and what is the extent of the disease?

What specific type of vasculitis is this? Is this a large-vessel, medium-vessel or small-vessel vasculitis?

Consider mimics of vasculitis

Vasculitis mimics should be excluded first.

- Infections
- Embolic disorders
- Malignancy
- Drugs

In particular, infections deserve careful attention, as they are major mimics of vasculitis and would be aggravated by medication aimed to suppress vascular inflammation. Infective endocarditis should always be considered. It is known to mimic vasculitis. Although the endocardium is the primary site of infection, it often results in multisystem manifestations, involving several organs. Bacteraemia and peripheral embolic events are common. Circulating immune complexes may lead to immune responses most often affecting the skin, the kidney and the central nervous system.

Differential diagnosis is not always simple.

Think about the clinical and laboratory findings you will expect to find in both a vasculitis and an infection

Table 2. Clinical and laboratory similarities between infection and vasculitis

Clinical findings:

- B-symptoms (fatigue, weight-loss, fever)
- myalgia
- arthralgia

Laboratory findings:

- normocytic normochromic anaemia
- lymphocytosis
- thrombocytosis
- elevated ESR
- raised CRP

Like infections, other conditions can mimic vasculitis. Mimics of vasculitis lead to ischemia and systemic signs and symptoms, but are caused by other physiological mechanisms. They are frequently entitled pseudo-vasculitis or vasculitis-like syndromes.

An embolism from an atrial myxoma or cholesterol emboli from an atheroma are examples of embolic diseases that can mimic vasculitis.

Thrombotic disorders such as antiphospholipid syndrome, thrombotic thrombocytopenic purpura and sickle cell disease can cause thrombosis and thus mimic vasculitis. Amyloid angiopathy and fibromuscular dysplasia are non-inflammatory vessel wall disorders causing ischaemic organ damage. Some conditions like end-stage renal failure and hyperparathyroidism can be associated with a livedo reticularis-like rash which can be mistaken as a sign of vasculitis.

Drugs can induce vasoconstriction and ischaemia. These include ergots, cocaine and phenylpropanolamine. Some drugs can cause coagulopathy and in this way mimic the vasculitis e.g. Warfarin.

Malignancy will often have B-symptoms and basic laboratory findings such as normocytic normochromic anaemia, lymphocytosis, thrombocytosis, elevated ESR and raised CRP. Radiological findings of multi nodular lung shadows due to metastasis can suggest GPA.

Consider secondary vasculitis

Secondary vasculitis includes the same diagnostic headings as the mimics, but in addition, several of the connective tissue diseases need to be considered.

- Infections
- Drugs
- Malignancy
- Connective tissue diseases

Consider infections which cause secondary vasculitis

Infections

Many infections can result in secondary vasculitis; the majority are viral.

Hepatitis B and C, Parvovirus B19, Human immunodeficiency virus (HIV), Cytomegalovirus (CMV) and Epstein-Barr virus (EBV) are examples of viral conditions which are known to cause secondary vasculitis. Hepatitis C has a special association to secondary vasculitis. Cryoglobulins can be found in many of the primary or secondary vasculitis.

Infections with *Salmonella*, *Streptococcus pneumoniae*, *Clostridium septicum*, *Chlamydia pneumoniae* and *Mycobacterium tuberculosis* can also result in vasculitis. Even parasites (e.g. *Ascaris*) and fungi (e.g. *Aspergillus*) have been associated with secondary vasculitis.

Many clues suggest the hypotheses that infections may be the cause of true primary vasculitis, but we will leave this discussion to the modules on vasculitis.

Drugs

Drugs from almost every pharmacological class have been mentioned as the cause of secondary vasculitis. Some have been shown in large clinical trials; others just in case reports. Hydralazine, propylthiouracil, minocycline and related agents are well described ANCA-associated drugs, while leukotriene inhibitors, sulfasalazine, D-penicillamine, ciprofloxacin, phenytoin, clozapine, allopurinol and several others are suspected of causing secondary vasculitis without ANCA association. Intoxication (drug abuse) with cocaine, morphine and others can also result in secondary vasculitis.

The clinical presentations are highly variable, from small vessel hypersensitivity vasculitis and leukocytoclastic vasculitis to conditions resembling granulomatosis with polyangiitis (GPA), polyarteritis nodosa (PAN) and eosinophilic granulomatosis with polyangiitis (eGPA). However, cutaneous manifestations, such as palpable purpura and maculopapular rash, are the most common manifestations of drug induced vasculitis. The lesions more frequently affect the lower part of the legs and are almost always synchronous with respect to the time of onset and rate of progression, as opposed to primary vasculitis where lesions occur at different times and progress independently.

Musculoskeletal symptoms are common and involvement of the kidneys, liver, CNS and other organs can occur.

Diagnosing a drug induced vasculitis might be very difficult. A comprehensive drug history should be obtained for all patients with vasculitic manifestations.

Malignant diseases such as solid tumours, myeloproliferative and lymphoproliferative disorders can be associated with secondary vasculitis.

Connective tissue diseases, especially rheumatoid arthritis (RA), SLE and primary Sjögren's syndrome are known to cause secondary vasculitis. An important clue is that the vasculitis usually appears late in the disease, which makes the diagnosis easier.

Inflammatory bowel diseases can also originate secondary vasculitis.

Confirming the diagnosis of vasculitis and assessing the extent of the disease

We have now discussed different diseases that mimic vasculitis or result in a secondary vasculitis looking at many similarities, but how do we exclude the mimics and secondary vasculitis from the primary vasculitis? And how do we separate isolated cutaneous manifestations from multisystem involvement?

Let us revert to our initial case:

A 45-year-old Caucasian male with a 3-week history of B-symptoms and a non-itching rash on the lower part of the legs looking like a leukocytoclastic vasculitis. He has possible involvement of his kidney and CRP is raised at 85 mg/l.

How will you continue the assessment of this patient?

The secret to the diagnosis is to systematically ask and look for symptoms or signs of the skin, muscle, nervous system or vital organ impairment pointing to local ischemia, arterial and venous thrombosis, arterial hypertension, bloody nose discharge, sight loss, mononeuropathy, pulmonary infiltration. Be aware that what might look like an isolated cutaneous vasculitis can be complicated by life threatening internal organ involvement and the need for immediate aggressive systemic treatment.

In the early stage of vasculitis, the diagnosis is especially difficult while late manifestations are often more specific.

Our patient could have a mimic of vasculitis, secondary vasculitis as well as primary vasculitis. In order to get closer to the diagnosis, you first have to exclude mimics and secondary vasculitis:

- Expand the history taken
 - Travel history
 - Drug history
- Full clinical examination
- Urine protein: creatinine ratio and urine microscopy

- Chest x-ray
- Basic blood screening (complete blood cell count, liver enzymes, CRP, ESR, creatinine)
- Electrocardiogram

Laboratory testing is only occasionally helpful in classifying vasculitis, but it is most important in excluding other diseases and determining organ involvement. Here you have to have all the former conditions in mind and undertake laboratory testing based on the history and clinical examination.

You may consider:

- Blood cultures
- Hepatitis B and C screening, CMV and Parvovirus B19
- HIV test
- Relevant testing for bacteria, fungi or parasites
- Serological tests
 - ANA, anti-double stranded DNA, rheumatoid factor, glomerular basement membrane antibody, creatine phosphokinase, complement factors (C3, C4)
 - ANCA (PR3/MPO)
 - Antiphospholipid antibodies
 - Lupus anticoagulant
 - Cryoglobulins
- Echocardiogram

Consider which basic tests you will need to explore organ involvement in vasculitis?

A detailed history and physical examination together with a chest x-ray, urine examination for protein and microscopy and basic laboratory tests will, for most patients without primary vasculitis, be sufficient to exclude systemic involvement.

Consider how you can confirm the diagnosis of primary vasculitis, once you have excluded mimics and secondary vasculitis

Confirming the diagnosis of primary vasculitis

The diagnosis of vasculitis is based on a combination of clinical, serologic, histological and angiographic parameters.

Histological confirmation of vasculitis should be sought in most cases by undertaking a tissue biopsy. The site of biopsy is guided by clinical manifestations and by the likelihood of the results affecting treatment decisions. If there is an indication of kidney involvement (proteinuria), kidney biopsy will be preferred. Other favoured sites are skin, temporal artery, muscle, nasal mucosa, lung, sural nerve and testis. Although pathological proof of vasculitis should be looked for, it is not mandatory for the final diagnosis. In the context of a clinical picture suggestive of GCA, a negative temporal artery biopsy does not rule out GCA. Likewise, a full blown picture of ANCA associated vasculitis does not necessarily require pathological confirmation.

In patients with large or medium vessel vasculitis there is commonly great difficulties verifying the biopsy and an angiography, computed tomography angiography (CTA), magnetic resonance angiography (MRA) or even positron emission tomography scan (PET scan) should be considered. For example, gastrointestinal tract vasculitis or renal artery involvement may show in anCTA. CTA can reveal characteristic images, such as multiple microaneurysms in patients with polyarteritis nodosa (PAN). MRA of the thoracic aorta may show stenosis, occlusion or aneurysm formation in patients with large vessel vasculitis such as Takayasu's arteritis.

Which specific type of vasculitis is this?

A in depth approach to this question is better served by the modules on vasculitis. Here, we will just give a short introduction.

Knowledge of the aetiology and pathogenesis of vasculitis is still limited. The group is very heterogeneous and there is considerable clinical overlap in their manifestations. Several attempts to classify have been tried. One of the most accepted is the Chapel Hill classification from 2012. It builds on microscopic findings, but also considers the size of vessels involved, and immunological markers (e.g. ANCA in GPA) and immunohistological findings (e.g. IgA-dominant immune deposit in Henoch-Schönlein purpura). Many other manifestations help with diagnosing the type of vasculitis such as demographic associations, clinical features and histological findings (Table 3).

Table 3. Clinical symptoms, demographic associations and size of vessels involved

Clinical symptoms	Age	Sex ratio (M:F)	Ethnic origin	Type of vasculitis	Vessel size
Arm or leg claudication, decreased pulses, subclavian/aortic bruit	15-40	1:9	Asian > others	Takayasu's arteritis	Large
Headache, jaw claudication, shoulder girdle/hip pain, diplopia	>50	1:3	Caucasian >> others	Giant cell arteritis	Large
Weight loss, livedo reticularis, mono/poly neuropathy, hypertension	40-60	2:1	Any	Polyarteritis nodosa	Medium
Fever, conjunctivitis, cervical lymphadenopathy, mucositis, polymorphous exanthema	1-5	1.5:1	Asian > white > others	Kawasaki's disease	Medium
Sinusitis, oral ulcers, otitis media, haemoptysis, active urinary sediment	30-50	1:1	Any	GPA	Small
Asthma, atopic history, mono/poly neuropathy, pulmonary infiltrates, eosinophilia	40-60	2:1	Any	eGPA	Small
Palpable purpura, abdominal pain, bloody diarrhoea	5-20	1:1	Any	Henoch-Schönlein purpura	Small
Oral and genital ulcers, folliculitis, uveitis, thrombophlebitis	20-35	1:1	Middle Eastern > others	Behçet's syndrome	Small
Palpable purpura, maculopapular rash	30-50	1:1	Any	Leukocytoclastic vasculitis	Small

GPA Granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis); eGPA Eosinophilic granulomatosis with polyangiitis (formerly known as Churg-Strauss syndrome)

IN-DEPTH DISCUSSION II

Idiopathic inflammatory myopathy (IIM)

Clinical case:

The patient, a 56-year old female, is a married bank accountant. She is a non-smoker and reports of no previous health problems.

Her history is:

“During the last three months it has become increasingly difficult to walk up the stairs to my apartment on the 3rd floor. I have increasing problems combing my hair and occasionally I have found it difficult to swallow certain types of food, particularly larger chunks of meat and a dry bread. I have noticed some sort of rash on my elbows and knees and when I go for a walk I oft get a feeling of breathlessness.”

Clinical examination:

A middle aged woman, normal weight. No obvious muscular atrophy. She has a violet erythema and papules on the dorsal side of metacarpal and interphalangeal joints and skin changes on the extensor side of the elbows and knees joint that resemble psoriasis plaque. Her hands are marked by dryness and scaling and hyperkeratosis most apparent of the thumbs and rash and dryness on the eyelids.

Her blood pressure is 132/84 mmHg, temperature 37.0°C. Lung auscultation reveals low sounding crackles over the basal parts. Muscle strength evaluation is abnormal. She has problems elevating her arms over head and has problems rising from sitting position. Her finger grip strength is normal.

Blood tests:

Hgb 10.8 g/dL, creatinine 65, albumin 37, ASAT 450, creatinine kinase 3,500, ESR 69 mm/h, C-reactive protein 12 mg/L.

Try to formulate a one-sentence representation defining the case in abstract terms.

56-year female who, over the last three months has developed progressive and symmetrical weakness in proximal muscle groups, respiratory symptoms and findings, and skin abnormalities consisting of Gottron's sign and papules, heliotrope rash and mechanic hands.

DIAGNOSTIC APPROACH

Step one: Is the diagnosis of idiopathic inflammatory myositis suspected?

Do the clinical symptoms, signs correlate to the diagnosis of idiopathic inflammatory myositis (IIM)?

In table 1 symptoms and signs of myositis are reviewed. Confer to the clinical case.

Table 1. Symptoms and signs of myositis

- **Reduced muscle strength**

- proximal, distal or both?
- symmetric or asymmetric?
- Time of involvement?
- Muscle atrophy?

- **Dysphagia**

Problems initiating swallowing and/or aspirations.

- **Skin involvement**

- Gottron's changes, shawl sign, heliotrope rash, mechanical hands, periungual erythema, erythroderma?
- Calcinosis cutis?

- **Other extra muscular involvement**

- From joints: arthritis?
- From lungs: interstitial lung disease?
- From the heart: myocardial affection?

Which investigations would you do
1) to confer the diagnosis of myositis, 2) to classify the myositis
3) and chart the severity of the myositis

In table 2 the most common investigations are reviewed.

Table 2. Investigations in myositis

- **Blood tests:**
 - **Haematological status, inflammation markers (ESR and CRP)**
 - **Markers of muscle damage; increased levels of Creatinine kinase (CK) and myoglobin** are the most specific muscle markers. Levels of Lactate dehydrogenase (LDH), aspartate aminotransferase (AST) and alanine aminotransferase (ALT) and aldolase may also be increased, but less muscle specific.
 - **Serologic tests** including antinuclear antibodies (ANA), antibodies against extractable nuclear antigens (anti-Ro/SSA, anti-La/SSB, anti-Sm and anti-RNP), and “myositis specific or associated” antibodies (e.g. anti-histidyl-t-RNA synthase (anti-Jo-1), anti-PL12, PL7, OJ, EJ in addition to anti-Mi-2, SAE, NXP-2, TIF1γ, anti-MDA5, anti-HMGCR and anti-SRP)
- **Electromyography (EMG)** is a diagnostic procedure to assess muscles and motor neurons.
- **Muscle imaging, most commonly by Magnetic Resonance Imaging (MRI)** Can be used to guide muscle biopsy site.
- **Standardized assessment of muscle function and strength by manual muscle tests** as a standardized tool of evaluation and follow-up.
- **Muscle biopsy to confirm the clinical diagnosis and to classify the muscle inflammation**
- **Assessment of swallowing function by dynamic X-ray, often supplemented with gastroscopy and/or manometry.**
- **Investigations of lungs** if there is a suspect of interstitial lung disease
 - **high resolution CT scan (HRCT)**
 - **Pulmonary function tests**
 - **Echocardiography and/or MRI of heart**
- **Other**
 - **Nailfold Capillaroscopy** is a non-invasive method to evaluate vascular dysfunction.

What would be the most likely diagnosis?

Table 3. The clinical spectrum of idiopathic inflammatory myopathy (IIM)

- Polymyositis (PM)
- Dermatomyositis (DM)
- Juvenile dermatomyositis (jDM)
- Necrotising myopathy
- Inclusion body myositis (IBM)
- Amyopathic/hypomyopathic dermatomyositis
- Myositis in overlap syndromes
- Paraneoplastic myopathy

The clinical spectrum of idiopathic inflammatory myositis is listed (table 3).

Patients with polymyositis (PM), dermatomyositis (DM) and necrotising myopathy will typically develop symmetrical and proximal muscle weakness over a period of weeks to few months. Patients with inclusion body myositis (IBM) are typically older than the PM/DM patients (mean age at onset 65-70 years) and will often have a slow progressive weakness that may be asymmetric at least initially and affects both proximal and distal muscle groups. In addition, their creatinine kinase (CK) values are usually lower than the values in patients with PM, DM or necrotising myopathy.

Proximal oesophageal affection does not clinically distinguish between the IIMs. By performing dynamic x-ray barium swallow study patients with IBM, in contrast to patients with the other IIMs, often have cricopharyngeal dysfunction or spasm. In select cases this cricopharyngeal muscle dysfunction can be treated with selective myotomy, oesophageal dilatation and/or Botox injections.

Dermatological manifestations of dermatomyositis can in some cases be mixed with psoriasis, but skin biopsy could separate. Our patient had skin changes typical for dermatomyositis. The combination of prototypical skin changes, progressive symmetric proximal muscle weakness and high CK is highly suspect of DM.

DIAGNOSTIC APPROACH

Step two: The diagnostic strategy

Having considered the possibility of idiopathic inflammatory myositis (IIM)

We suggest you try to answer the following questions in succession:

Is this a condition that could mimic the presentation of IIM?

How do I confirm the diagnosis IMM and what is the extent of the disease?

The case would probably have been more difficult to resolve if the skin changes were absent. There are several important differential diagnoses to consider in patients with muscle weakness and/or high muscle enzymes (table 4).

Most of the metabolic myopathies and muscle dystrophies are diagnosed at an early age, but in some cases, the clinical picture can evolve later in life. It is therefore important to retrieve information about relatives with muscle diseases.

A thorough review of current and earlier medication, alcohol use and illicit drug abuse is important. Screening for endocrine myopathy (by assessment of thyroid and adrenal hormone levels) and electrolyte disorders.

It is important to evaluate the patient for systemic autoimmune disease as mentioned (table 4).

Table 4. Disorders that mimics idiopathic inflammatory myositis (IIM)

- **Metabolic myopathies**
 - **Disorders of the glycogen metabolism**
 - McArdle's disease
 - Lysosomal acid maltase deficiency (GSD II)
 - Etc.
 - **Disorders of the lipid metabolism**
 - Carnitine deficiency syndromes: Primary systemic or muscle carnitine deficiencies and secondary carnitine deficiencies
 - Fatty acid transport disorders: Carnitine - palmitoyltransferase 1A deficiency / - acylcarnitine translocase deficiency / - palmitoyltransferase 2 deficiency
 - Myoadenylate deaminase (MADA) deficiency, a disorder of purine metabolism.
 - Lipin-1 deficiency
 - Multiple acyl-CoA dehydrogenase deficiency (MADD)
 - **Mitochondrial myopathies:** a dysfunction in the mitochondria that affect the aerobic metabolism.
- **Muscle dystrophies** is a group of several different muscle disorders that also can involve other organ

systems by abnormal genes that interfere with the production of muscle proteins.

- **Facioscapulohumeral muscular dystrophies (FSHD)**
 - **Becker and Duchenne muscular dystrophies (BMD and DMD)**
 - **Limb-girdle muscular dystrophy (LGMD)**
 - Calpainopathies by mutations in the calpain-3 gene.
 - Dysferlinopathies by mutations dysferlin gene
 - Sarcoglycanopathies
 - Laminopathies
 - Caveolinopathies are caused by mutations in the caveolin 3 gene
 - **Emery-Dreifuss muscular dystrophy (EDMD)**, also known as humeroperoneal muscular dystrophy
 - **Myotonic dystrophy type 1 (DM1) and type 2 (DM2)** are autosomal dominant, multisystem disorders.
- **Endocrine myopathies**
- Hypothyroid or hyperthyroid myopathies
 - Cushing syndrome or Addison's disease related myopathies
 - Myopathies associated with hyperaldosteronism.
 - Hyperparathyroid myopathies
 - Hyperaldosteronism
- **Electrolyte disorders:** Hypo-/hyperkalaemia, hypo-/hypercalcemia, hypo-/hypernatremia.
- **Drug induced myopathy** that either causes a direct myotoxicity or secondary immunologically mediated myopathy or both.
- Statin myopathy. Statins can cause both a toxic and an immunologically mediated myopathy with symptoms from myalgia, to myopathy, myositis and necrotising myopathy that can be associated with anti-HMG-CoA reductase antibodies.
 - Corticosteroid myopathy
 - Colchicine myopathy
 - Hydroxychloroquine/chloroquine myopathy with typical histological changes with myeloid and curvilinear bodies.
 - Zidovudine myopathy
 - Alcohol myopathy with both acute and chronic forms that are associated with longstanding alcoholism.
 - Cocaine myopathy can lead to massive and life-threatening rhabdomyolysis
 - Interferon alpha
 - D-penicillamine
 - Etc.
- **Neuromuscular diseases**
- *Anterior horn lesions* as seen in motor neuron diseases like amyotrophic lateral sclerosis (ALS), spinal muscular atrophy (SMA) and poliomyelitis.
 - *Secondary to peripheral nerve lesions* as in polyneuropathies or mononeuropathies /mononeuritis multiplex.
 - *Involvement of neuromuscular junction* as in myasthenia gravis or Lambert-Eaton syndrome.
- **Myopathy of systemic rheumatic disease**
- Autoimmune diseases – Systemic sclerosis (SSc) with myositis overlap. Mixed connective tissue disease (MCTD). Also primary Sjögren's syndrome (pSS) and systemic lupus erythematosus (SLE).
 - Vasculitis with muscle involvement as part of systemic vasculitis.

- Other systemic disease as – sarcoidosis
- **Infectious myositis**
 - **Pyomyositis** is a purulent infection of skeletal muscle.
 - **Myopathies associated with viral infections** can be caused by: HIV, Coxsackie virus, Epstein-Bar virus, Hepatitis B and C, Influenza A and B, Varicella zoster virus, Cytomegalovirus etc.
 - **Parasitic myopathies** can be caused by: toxoplasma gondii, Trypanosoma cruzi, Schistosoma, Microsporidia etc.
 - **Helminthic myopathies** can be caused by: e.g. Trichinella, Echinococcus.

Paraneoplastic myopathy

How do I confirm the diagnosis IMM and what is the extent of the disease?

The most widely used diagnostic criteria for DM and PM in clinical research is the Peter and Bohan criteria presented in 1975. There are five items in the criteria, each giving one point. Based on the total score, PM and DM is divided into; 'definite', 'probable' and 'possible' cases. The disadvantage of the Peter and Bohan criteria is that they may allow patients with diseases that mimic myositis to be classified as having an inflammatory myopathy. In addition, IBM may also be misclassified as polymyositis. The New European-American IIM classification criteria are in development, and are expected to be launched by the end of 2016.

The Peter and Bohan criteria antedated the discovery of myositis specific autoantibodies (MSA). This is a major drawback as the MSA have proven to be very valuable as diagnostic and prognostic tools in myositis. For example; necrotising myopathy is associated with the presence of anti-HMGCR and anti-SRP antibodies. The anti-synthetase antibodies (anti-Jo-1, PL12, PL7, OJ, EJ, HA, KS Zo) are associated with interstitial lung disease (ILD). Anti-MDA5 antibodies are rare and are associated with necrotizing dermatomyositis with severe ILD. Anti-Mi-2 antibodies are associated with DM. Anti-NXP-2 and anti-TIF1y antibodies are associated with cancer in adult patients (table 1 and further the chapter for inflammatory myositis).

Are there “red flags” or alarming aspects concerning our patient.

Name two aspects that would concern you regarding the patient.

1.

The major concern is that the patient has symptoms and findings suspect of myositis-associated interstitial lung disease (ILD).

High resolution CT thorax was performed and showed finding consistent with ILD. Pulmonary function test revealed restrictive lung disease with FVC 78%, FEV1 79% and DLCO 75% of expected values.

Serologic test showed a high titre of anti-histidyl-t-RNA synthase (anti-Jo-1) antibodies, consistent with anti-synthetase syndrome that can coincide with dermatomyositis.

Several studies have shown that ILD is a major determinant of mortality and morbidity in myositis.

#2

Adult-onset dermatomyositis carries an increased risk of malignancy, but this is not the case in juvenile onset dermatomyositis. Increased risk has been confirmed in several population-based studies, with standardized incidence ratios of cancer ranging from 2.0 to 6.0. The association between cancer and inflammatory myopathies has been extensively reported in dermatomyositis (DM), but in lesser degree in polymyositis (PM). Inclusion body myositis (IBM) have shown conflicting results regarding cancer risk. The patients are generally older and recent studies have not confirmed an increased risk of cancer compared with age matched background population. Amyopathic dermatomyositis is reported to have a similar risk as DM and necrotizing myopathy is reported to be associated with cancer.

In Western countries, common malignancies associated with DM include; ovarian, lung, pancreatic, gastric, and colorectal cancers, while among patients from Southeast Asia, DM is seen strongly associated with nasopharyngeal carcinoma. Cancer is most commonly recognized within 2 years of the diagnosis. The risk factors for underlying malignancy in myositis include; older age of onset, resistance to treatment, severe cutaneous involvement with ulcerations, leukocytoclastic vasculitis and severe and therapy resistant muscle disease. Paraneoplastic myopathy has been associated with anti-NXP-2 (anti-p140) and anti-TIF1γ (anti-p155, anti-p155/140) antibodies. Screening for underlying malignancy is mandatory in patients above the age of 40 with new diagnosis of inflammatory myositis. Currently, there is no consensus on how extensive such

screening work-up should be. A careful history, a complete physical examination, appropriate laboratory tests and age-appropriate cancer screening are indicated. Any abnormalities detected that may signal the presence of an occult cancer should be further

Early arthritis: diagnosis and management

Sofia Ajeganova, Anca I Catrina, Tom W.J. Huizinga

A previous version was co-authored by Jackie Nam, Bernard Combe, Paul Emery

LEARNING OUTCOMES

- ➔ Discuss the term early arthritis and its significance
- ➔ Describe and evaluate the measures used in the diagnosis of early arthritis (clinical, radiological and laboratory)
- ➔ Describe and discuss the prognostic factors in early arthritis
- ➔ Outline and evaluate the treatment modalities (pharmacological and non-pharmacological) available for the management of early arthritis
- ➔ Discuss the aims of treatment and the outcome measures used to evaluate treatment efficacy

1 Introduction

Rheumatoid arthritis (RA) is the most common and serious inflammatory arthritis. Untreated it results in joint destruction, functional impairment and increased mortality. The outcome of the disease, however, has improved considerably in recent years with early diagnosis, the availability of effective treatments and the recognition that early intensive treatment strategies result in better outcomes. Recently, the treat-to-target strategy study in recent-onset RA has been demonstrated that treatment targeted to low disease activity determines long-term outcomes after 10 years. Drug-free remission, prevention of functional deterioration and clinically relevant radiographic joint damage, and normalized survival, comparable with survival of the background general population, are realistic outcomes (Markusse et al, 2016).

In practice, patients with inflammatory arthritis should be seen and recognized early and treated at the earliest opportunity. Clinicians must differentiate the early features of RA (an inflammatory arthritis that has the potential to become progressive and destructive) from those arthritis that will remit spontaneously, and from diseases that may present with similar clinical features of arthritis - for example, systemic lupus erythematosus (SLE) and Sjögren's syndrome. Decision about the best therapeutic strategy and adapting the therapy to an individual patient are required. The goal of treatment is early suppression of inflammation and ideally, establishing remission as early as possible in order to prevent joint damage, disability and the long-term complications of the disease. The hope for the future is that interventions will be so timely, individual and effective that drug-free remission with resolution of symptoms of arthritis and normalized function status is achieved. Nowadays this outcome is increasingly achievable, indicating that RA-chronicity can be influenced (Ajeganova et al, 2016).

This chapter will provide some background and an approach to the diagnosis and treatment of early arthritis. Other reviews on the topic: Combe et al, 2009; Finckh, 2009; Raza and Filer, 2009*; Hoes et al, 2010; Klareskog et al, 2010*; Scott et al, 2010; Breedveld, 2011; de Vries et al, 2011; Dekkers et al, 2016.

2 Background

2.1 The rationale for early management

Although definitions vary, remission implies a state without damaging and disabling. Spontaneous remission without treatment is rare in RA (Wolfe and Hawley, 1985; Eberhardt and Fex, 1998). In most untreated patients, the disease persists and results in joint damage, functional decline and premature mortality. However, several studies have reported that drug (DMARD)-free sustained remission can be achieved in approximately 10-15% of the patients with early RA (Wolfe and Hawley, 1985; van der Woude et al, 2009; van der Woude et al, 2012).

The joint damage and loss of function in RA occur early in the disease process. Radiographic outcome studies have shown that 70% of patients with recent-onset RA develop bony erosions within the first 3 years (van der Heijde et al, 1995). Importantly, already within 3 months of disease onset, 25% of patients have erosions evident on X-ray examination (Nell et al, 2004). More sensitive imaging techniques such as magnetic resonance imaging (MRI) and musculoskeletal ultrasonography (MSUS) have confirmed evidence of damage within weeks of onset of symptoms (McGonagle et al, 1999; Wakefield et al, 2000). The MSUS detects at least 1.4-fold more patients with erosions than X-ray examinations (Funck-Brentano et al, 2009), and the prevalence of bone erosions detected by MSUS is reported in as many as 60% of early RA-patients (Tămas et al, 2014).

The presence of early radiographic erosions predicts the future progress of joint damage. The bone erosions seen on MSUS are correlated with later development of X-ray erosions (McQueen et al, 2001), and baseline and early changes in MRI measures predict later X-ray and MRI progression (Baker et al, 2014). Of note, persistent MRI bone marrow oedema, but not persistent MRI synovitis, is strongly associated with erosive progression, independently of local synovitis (Nieuwenhuis et al, 2016).

However, the role of MSUS and MRI imaging techniques in diagnosis of early arthritis, assessment of disease activity and therapy choice in clinical practice is so far unclear. Thus, adding information on the presence of MRI detected bone marrow oedema and erosions increases sensitivity but considerably decreases specificity of 2010 EULAR/ACR criteria for RA, and does not improve the accuracy and discriminative ability of the criteria (Nieuwenhuis et al, 2015). MSUS-guided assessment of disease activity on the top of clinical examination did not result in better clinical and MRI outcomes than DAS-guided assessment, though MSUS-driven therapy led to more intensive treatment (Dale et al, 2016).

Several studies have shown that a delay in treatment commencement is associated with poorer outcomes. In a meta-analysis of 12 studies in patients with RA and symptom duration of <2 years, an average 9-month delay with starting disease-modifying antirheumatic drugs (DMARDs) significantly increased subsequent radiographic progression (Finckh et al, 2006). In an early arthritis cohort, the first assessment by a rheumatologist of patients with symptom duration ≥ 12 weeks was associated with a 1.3-times higher rate of joint destruction over 6 years and a hazard ratio of 1.87 for not achieving DMARD-free remission, as compared with assessment in <12 weeks after symptom onset (van der Linden et al, 2010). A recent meta-analysis of 18 cohort studies and randomised controlled trials has confirmed that that prolonged symptom duration is associated with radiographic progression and a lower chance for DMARD-free sustained remission (van Nies et al, 2014). Although we have learned last years about the importance of early initiating of DMARDs, the referral of the persons with suspected inflammatory arthritis should be also early. The assessment by a rheumatologist is however delayed by about 18 weeks in patients having RA or spondyloarthritis, and only 31% of the RA patients are assessed in <12 weeks of symptom onset (van der Linden et al, 2010).

As most patients with RA will have persistent disease, as joint damage occurs early and as it is expected that therapy delay results in worse outcomes, RA should be diagnosed and treated early. The question remains 'how early is early'?

2.2 Window of opportunity

The crucial therapeutic goal is to delay and prevent, where possible, progression of undifferentiated arthritis or very early RA. The concept of a 'window-of-opportunity' suggests that there is a limited period early in the course of the disease when the disease process can be altered or maybe even reversed with a complete return to normality. The start of treatment with DMARDs during this period may have a much greater effect in halting disease progression and make a real difference in the outcome of the patient than treatment at a later stage (Cush, 2007). It is expected that implementation of the new EULAR/ACR criteria for RA diagnosis can help to identify early RA patients and thence to start therapy as soon as possible in order to reach remission and prevent damage.

The cut offs between 'early' and 'established' RA have progressively decreased over the past decades. Previously, the cut-off <5 years after symptom onset was used to define an early disease. By the 1990s, symptom duration of <12–24 months was considered early. This duration was chosen because by 2 years up to 70% of patients treated conventionally may have erosive disease. Currently, 'early RA' is defined as disease duration less than 1 year. It is suggested that very early RA - that is, within the first 12 weeks of symptom onset - may present an immunopathologically distinct disease phase compared with later RA-disease (Raza et al, 2005). Thus, the early RA period is divided into 'very early RA' with disease duration < 3 months and 'late early RA' with the duration of symptoms from 3 to 12 months.

The treatment studies have evaluated the concept of very early window of opportunity. A non-blinded study of a single dose of glucocorticoid in 63 patients with mild early inflammatory arthritis of median duration of 20 weeks found that the strongest predictor of disease remission at 6 months was a symptom duration of <12 weeks at the time of treatment (Green et al, 1999). Clinical and radiographic outcomes were significantly better in 20 patients with RA who started DMARDs 3 months after disease onset (very early) compared with 20 patients who started therapy after a median of 12 months' (early) (Nell et al, 2004). In this study, a significant difference in the DAS28 improvement in favour of the very early treatment group was evident already after 3 months of DMARD therapy, and remission was achieved in 50% in the very early group compared with only 15% in the early group. The importance of early treatment has been also demonstrated in the randomized controlled trial of 417 patients with early RA treated with methotrexate (MTX) +/- etanercept. In this study, the patients with symptom duration of <4 months achieved significantly better disease control with a 40% increase rate of remission, lower disease activity scores and more likely did not have radiographic progression compared to the patients who started treatment >4 months to 2 years (Emery et al, 2012). A recent analysis in

two cohorts which included 1271 early RA patients followed for 5 years has convincingly shown that the shape of the associations between symptom duration at treatment initiation and persistence of RA defined as drug-free remission is not linear, suggesting the presence of a confined period in which RA is more susceptible to treatment, and this favourable period was discriminated at 15-20 weeks of symptom duration (van Nies et al, 2015).

Inflammatory arthritis may begin much earlier than it is now could be detected. It is proposed that the development of RA includes several distinct phases, which might or might not occur as a disease continuum, from pre-clinical asymptomatic to clinically evident phase of undifferentiated arthritis (UA) and RA. The auto-antigens triggered by innate, environment, lifestyle and stochastic stimuli can lead to formation of non-matured autoantibodies. In the genetically susceptible persons, in the phase just before arthritis development, the autoantibody response matures as reflected by increasing titers and extensive isotypes and affinity spreading (Hensvold et al, 2015; Dekkers et al, 2016). It is not known whether persons during this phase already experience arthralgia.

Several serological abnormalities have been shown to present years before the onset of clinical arthritis, such as presence of rheumatoid factor (RF) and antibodies to citrullinated peptide (ACPA) (Rantapää-Dahlqvist et al, 2003) and raised levels of high sensitivity C-reactive protein (CRP) (Nielen et al, 2004). Structural changes have been detected by MSUS and arthroscopy in joints without clinical synovitis in patients with early RA (Conaghan et al, 2004). A study in 150 patients with clinically suspect (inflammatory) arthralgia followed for ≥ 6 months have demonstrated that age, localization of initial symptoms in small and large joints (compared with small joints only), C-reactive protein level, ACPA-positivity and subclinical MRI inflammation associates with further development of clinical arthritis. ACPA-positivity and MRI inflammation were most strongly associated with arthritis development (hazard ratios of about 5 to 6). In this study, subclinical MRI inflammation preceded clinical arthritis with a few months, and only 6% of persons developed RA in absence of MRI inflammation (van Steenbergen et al, 2015).

2.3 The challenges of early disease

The first few weeks or months of symptoms, therefore, represent an important therapeutic window in patients with very early synovitis who will develop RA. However, treating patients within this phase presents several challenges:

1. Assessing patients with inflammatory arthritis early;
2. Predicting which patients with early synovitis will develop RA and thus require treatment;
3. Determining how such patients should be treated.

As there is no single diagnostic test, a combination of clinical features and laboratory tests is used to make the diagnosis of RA. The 1987 American College of Rheumatology (ACR) classification criteria had previously been used to define RA. However, as these criteria were developed in patient populations with longstanding definite disease, they do not perform well for the diagnosis of recent-onset RA. In a systematic review of literature published between 1988 and 2006, the 1987 ACR criteria when applied in early RA have sensitivity ranging from 40 to 90% and specificity from 50 to 90% (Banal et al, 2009). The 1987 ACR criteria have poor sensitivity in early RA disease i.e. patients with RA may not fulfil these criteria. Because of relatively low specificity, other arthritis such as post-viral arthropathies and spondyloarthropathies may satisfy the ACR criteria.

The poor performance of 1987 criteria in early RA coincided with a shift in the focus in RA from 'established' to 'early disease', growing evidence that time to treat is a key driver of outcomes, the advent of ACPA test and an explosion of targeted biologic therapies. A collaborative initiative between ACR and EULAR to define RA at an early stage led to the development of new classification criteria for RA (Aletaha et al, 2010*). The emphasis of the 2010 ACR/EULAR RA classification criteria is on identifying patients with a short duration of symptoms and poor prognosis who will benefit from early diagnosis and early initiation of DMARD therapy. These criteria were meant to be applied to patients newly presenting with undifferentiated inflammatory synovitis and incorporate factors that best discriminate between those patients who are and those who are not at high risk for persistent and/or erosive disease. The criteria were satisfied in 87-97% of the patients where physicians initiated methotrexate (not meant to be used for diagnostic purposes).

According to the new 2010 ACR/EULAR criteria, classification as 'definite RA' is based on the clinical evidence of synovitis (i.e. swelling) in at least one joint and absence of an alternative diagnosis better explaining the synovitis (for example, SLE, psoriatic arthritis and gout). Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. The distal interphalangeal joints, the first metatarsophalangeal joint, and the first carpometacarpal joint are excluded as these joints are typically involved in osteoarthritis. Synovitis should not be better explained by another diagnosis - for example, SLE, psoriatic arthritis and gout. Classification as 'definite RA' is then based on achieving a total score of ≥ 6 out of possible 10 from individual scores in four domains (table 1): (A) number and site of involved joints (score range 0–5); (B) serological abnormality (range 0–3); (C) raised acute phase response (range 0–1) and (D) symptom duration (range 0–1) (table 1). These criteria do not include features typical of late RA-disease, i.e. symmetry, rheumatoid nodules and radiographic changes. There is no longer requirement of >6 weeks of symptom duration. The criterion of morning stiffness has been omitted and the serologic marker of ACPA is included. Patients with typical history of long-standing RA-disease, including those whose disease is inactive, patients with erosive disease with RA-type erosions on X-ray can be classified as RA even if they do not fulfil the criteria.

Table 1 2010 ACR/EULAR classification criteria for rheumatoid arthritis (RA)

A. Joint involvement	
1 Large joint	0
2–10 Large joints	1
1–3 Small joints (with or without involvement of large joints)	2
4–10 Small joints (with or without involvement of large joints)	3
>10 Joints (at least one small joint)	5
B. Serology (at least one test result is needed for classification)	
Negative RF AND negative ACPA	0
Low positive RF OR low positive ACPA	2
High positive RF OR high positive ACPA	3
C. Acute phase reactants (at least one test result is needed for classification)	
Normal CRP AND normal ESR	0
Abnormal CRP OR abnormal ESR	1
D. Duration of symptoms	
<6 Weeks	0
≥6 Weeks	1

Score-based algorithm: add score of categories A–D. A score of $\geq 6/10$ is needed for a definite classification of 'definite RA'.

High positive RF or ACPA is defined as >3 times upper limit of normal (ULN).

ACPA, antibodies to citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

In an internationally 'Stop-Arthritis-Very-Early' trial with ≤ 16 weeks of symptom duration, which included patients with a variety of diseases diagnosed during follow-up, has been shown that the predictive and discriminative abilities of the 2010 ACR/EULAR classification criteria were satisfactory and substantially better than that of the 'old' 1987 ACR criteria (Biliavska et al, 2013). The performance of the 2010 ACR/EULAR classification criteria has been tested in patients with early arthritis ≤ 12 months in the Rotterdam Early Arthritis Cohort (REAC) (Alves et al, 2011). In this study using the cut-point of 6 to start treatment 30% of persistent patients would not be treated, whereas 30% of the non-persistent patients would have been treated. Similar results have been reported in others studies (de Hair et al, 2012). Over diagnosis is of concern with the new RA criteria, and more patients whose disease eventually resolved without requiring DMARD are classified at baseline as RA according to the 2010 criteria than with the 1987 criteria, 8% vs 2% (Cader et al, 2011).

As rheumatologists see patients earlier in the course of disease, it has also become clear that a proportion of patients who present with an inflammatory arthritis may have an UA—a form of arthritis that does not fulfil classification criteria for a more definitive diagnosis. The outcome of these patients varies and the diagnosis may change in the first years of follow-up. Some patients will progress to RA, some to other rheumatic diseases, and some patients will continue to have undifferentiated disease or enter into remission (figure 1).

Estimates from the Leiden early arthritis clinic suggest that of all patients presenting with UA, 30% will remit, 30% will develop RA (based on the 1987 ACR criteria) and up to 20% remain undifferentiated (Verpoort et al, 2004).

Figure 1 Natural history of inflammatory arthritis

The key problem facing clinicians seeing patients with UA or early arthritis, therefore, is differentiating patients with self-limiting disease from those at risk of developing persistent inflammatory and erosive arthritis. This differentiation allows: 1) start of appropriate treatment for patients whose arthritic disease would progress and 2) avoidance of unnecessary treatment for those whose disease would resolve.

3 An approach to early arthritis

The following principles guide management strategies:

- Early recognition and treatment of patients with arthritis results in better long-term clinical outcomes.
- Regular monitoring of disease activity and treating to target (Smolen et al, 2010*), aiming for remission, improves outcomes.

The following steps have been suggested as an approach to the evaluation and treatment of patients with early arthritis (Combe et al, 2007*):

- Recognise the presence of inflammatory arthritis.
- Exclude diseases other than RA or UA that present as an early inflammatory arthritis (eg, SLE, psoriatic arthritis or other spondyloarthropathies).
- Estimate the risk of developing persistent or erosive irreversible arthritis in patients with RA or UA using a combination of clinical features, laboratory tests and imaging techniques.
- Institute treatment and monitor disease activity, escalating treatment as required in order to achieve a favourable outcome.

Although the golden standard is the determination whether arthritis i.e. synovitis is clinically present, it is now recognized that clinically suspect arthralgia (CSA) may constitute a pre-clinical phase of RA and is the earliest moment to clinically recognize arthralgia of the small joints that may progress to RA over time according to the clinical judgement of the rheumatologists (van Steenberg et al, 2015). In this study, out of 1558 patients with arthralgia presented to the rheumatology outpatient clinic, 102 patients had CSA (6.5%) according to the judgment of the treating rheumatologist at the first visit before any laboratory results were known. The main reason provided by the rheumatologists to consider the arthralgia as clinically suspect were joint pain that was worst in the early morning and improved with movement during the day, the presence of morning stiffness for ≥ 60 min, and a positive family history for RA. Subclinical inflammation as measured by MRI (present in 44% of patients with CSA), autoantibodies and elevated CRP were predictive factors (see above 2.2) for development of arthritis.

Clinical evaluation remains the cornerstone for evaluating early arthritis: determining whether arthritis is present or not, differentiating between inflammatory or non-inflammatory disease and determining the aetiology of the arthropathy. Articular symptoms may be the presenting manifestation of many infectious, inflammatory or malignant conditions. The clinical features may also provide clues to identifying those at risk of developing persistent erosive disease (table 1).

A thorough history should be documented, detailing the distribution of the symptomatic joints, duration of symptoms and early morning stiffness (EMS), response to non-steroidal anti-inflammatory drugs (NSAIDs), any prodromal illness and associated symptoms. Family history is important for RA, psoriasis and other autoimmune diseases. Personal and past medical histories, including smoking history, should also be noted. A comprehensive examination of all systems should be performed.

Laboratory investigations and imaging are ancillary measures for the diagnosis and prognosis of patients presenting with early arthritis. It is important, to be aware of their limitations when interpreting the results (eg, avoid false reassurance that disease is absent when test results are normal). Imaging techniques are potentially helpful in this setting.

4 Identification of inflammatory joint disease

The clinical finding of joint swelling not caused by trauma or bony swelling should suggest a diagnosis of early arthritis, especially if at least two joints are affected and/or EMS lasts for ≥ 30 min. Hand or foot involvement is common in inflammatory arthropathies and is suggested by a positive metacarpophalangeal (MCP) (figure 2) or metatarsophalangeal 'squeeze test'. Early referral recommendations for newly diagnosed RA have been derived from prospective clinical investigations of prognostic factors, early arthritis cohorts and the consensus of the expert panel: ≥ 3 swollen joints, metatarsophalangeal/metacarpophalangeal involvement, and morning stiffness of ≥ 30 minutes (Emery et al, 2002). Of note, all symptoms and findings together should be taken into

account as there is no single test to identify early RA. Thus, a recent study has documented that a positive squeeze test is associated with local joint inflammation but the sensitivity of the test is low, indicating a high percentage of swollen joints with a negative squeeze test. When the squeeze test is used on its own, it is insufficient to detect early arthritis (van den Bosch et al, 2015). The diagnostic value of morning stiffness has been newly investigated in 5,202 arthralgia and arthritis patients. It has been shown that morning stiffness ≥ 60 min in arthralgia and early arthritis patients is associated with arthritis and RA respectively, which supports incorporation of morning stiffness in the diagnostic process (van Nies et al, 2015).

Figure 2 Metacarpophalangeal squeeze test: lateral compression of the forefoot

All new patients with symptoms of an inflammatory arthritis should be referred to a rheumatologist during the early phase of the disease, ideally within 6 weeks of symptom onset (Hyrich, 2008). As a proportion of patients who will develop severe persistent inflammatory arthritis have normal/negative examination results at symptom onset, they should be referred to the rheumatologist regardless of blood test results or radiographic findings. If tests are done in primary care, referral should not be delayed while waiting for results.

5 Identification of a definitive cause of an inflammatory arthropathy

5.1 Clinical features

While joint symptoms predominate early in RA, extra-articular manifestations of RA (nodules, keratoconjunctivitis sicca, etc.) are seldom present early in the disease. In other forms of polyarthritis, extra-articular manifestations may be present early and may precede the onset of synovitis, providing clinical clues to the diagnosis. This is particularly true for SLE (malar rash (figure 3), serositis), reactive arthritis (urethritis, conjunctivitis), psoriatic arthritis (psoriasis (figure 4), nail pitting or other nail changes) and sarcoidosis (lung involvement, fever) (Dao and Cush, 2006) (table 2).

Figure 3 Malar rash in a patient with systemic lupus erythematosus.

Figure 4 Psoriatic plaques.

Table 2 Differentiating diseases that present as an early arthritis

Arthritis	Personal history	Typical pattern of joint involvement	Joints affected	Associated features	Laboratory tests
UA (non-progressive)	F > M	Insidious, oligoarthritis	PIP, MCP, wrist, MTP, knee, ankle		↑CRP/ESR, may be normal
Rheumatoid arthritis	F > M; At any age, peak 30–55years	Insidious, progressive, symmetrical	PIP, MCP, wrist, MTP, knee, ankle	Early morning stiffness	↑CRP/ESR, may be normal RF+, CCP+
Spondyloarthropathy	Psoriasis, Urethritis or cervicitis, IBD. Family history of psoriasis or IBD	Persistent, asymmetrical, oligoarticular	DIP, PIP, knee, feet, spine	Psoriasis, nail pitting, uveitis, enthesitis, dactylitis	ESR/CRP may be normal More severe course in HLA-B27+
Systemic lupus erythematosus	F > M, young	Polyarticular, symmetrical, tend to be migratory, usually non-erosive	PIP, knee	Rash, serositis	Anaemia, ↑ESR CRP usually normal proteinuria, ANA+, dsDNA+
Dermatomyositis	F > M peak 40-60 years	Symmetrical non-deforming non-erosive	MCP, PIP, wrist, ankles	Proximal muscle weakness, dysphonia/dysphagia 'Mechanic's hands', erythema, eruptions, pruritus Pulmonary involvement	Muscle enzymes elevated Jo-1, myositis-specific autoantibodies Electromyography
Scleroderma	F > M	Acute or occasionally insidious, symmetrical or asymmetrical	MCP, PIP Tendon friction rubs (diffuse disease)	Hardening and tightening of the skin Raynaud	CRP/ESR may be normal ANA+, Scl70+, ACA+
Sjögren's syndrome	F > M		Intermittent symmetrical non-erosive polyarthritis of mainly small joints Recurrent monoarthritis or oligoarthritis	Dry mouth and eyes, fatigue Systemic manifestations Rheumatoid arthritis	ANA+ SSA+ SSB+ RF+ in 50-80% Hypergamma-globulinaemia

			Usually mild synovitis		
Polymyalgia rheumatica (PMR)	F ≥ M Caucasian >50 years, mostly >60 years		Hip and shoulder girdle PIP, wrist, knee occasionally	Widespread myalgia, fatigue, fever Prolonged morning stiffness	Anaemia, ↑ ESR/CRP Seronegative
RS3PE	M > F >50 years, peak >70 years	Acute	Acute bilateral pitting oedema of the back of the hands and/or feet Symmetrical polyarthritis, synovitis, tenosynovitis	No underlying systemic disease	CRP/ESR elevated RF negative HLA-B27 may be positive Can be paraneoplastic
Rubella	Rubella epidemic and no previous vaccination Recent (2–3 weeks) rubella vaccination	Acute oligoarthritis or polyarthritis, symmetrical	PIP, MCP, wrists, knee	Rash, lymphadenopathy, fever	Rubella serology (IgM) Virus isolation from nasopharynx or joint tissue
Parvovirus B19	F > M often a contact with a small child with Viral Infection	Acute	Symmetrical self-limiting predominantly MTP, PIP	Rash, malaise, ev myocarditis, myositis, hepatitis	Serology for Parvovirus PCR B19 DNA
Epstein-Barr virus			Monoarthritis knee polyarthralgia		Serology for EBV
Alpha viruses: Chikungunya virus CHIKV (sporadic epidemics globally), Ross River virus (Australia) Barmah Forest virus (Australia) O'nyong nyong virus Mayaro virus Sindbis virus Karelian fever (West Russia) Ockelbo virus (Sweden)	Mosquito-borne RNA viruses in endemic areas (Asia and Africa) Travel to endemic areas	Acute polyarthritis	Feet, ankle, fingers, wrists	Rash, fever, tendinitis and periarticular involvement	Serology for alpha viruses

Pogosta virus (Finland)					
Hepatitis viruses (HBV, HCV)	Hepatitis risk factors	Acute polyarthritis	Oligo- or polyarthritis PIP, MCP, wrist, knee, ankles	Fever Jaundice	↑ESR/CRP, ↑LFTs Hepatitis B and C serology
Retroviruses HIV		Reactive arthritis	Acute asymmetric oligo- or polyarticular, lower limb joints		Serology HIV-1 and HIV-2 RF, ANA, antiphospholipid antibodies may be present
		Undifferentiated spondyloarthritis	low back pain shoulders and ankles		
		HIV-arthritis	mono- of polyarticular knee and ankles		
Reactive arthritis					
Post-streptococcal	Peaks 8-15 and 20-40 years		Acute-onset, persistent or recurrent, symmetric or asymmetric Affecting any small and large joints and axial skeleton	Fever, myalgia common	ESR/CRP modestly elevated
Bacteria: Urinary bacteria: Chlamydia trachomatis, Mycoplasma genitalium, Ureaplasma urealyticum, E.coli	antecedent pharyngitis/ tonsillitis by group A streptococci (GAS)	Common symptoms involving the urethra, conjunctiva, and joints	Asymmetric monoarthritis or oligoarthritis of lower limbs		20-25% positive HLA-B27
Enteric bacteria: Salmonella, Shigella, Campylobacter, Yersinia, Clostridium difficile, Giardia lamblia, Tropheryma whipplei	Antecedent enteric or urogenital infection		Sacroiliitis, back pain, enthesitis, rash, ocular inflammation		↑ESR/CRP Serology, microscopy, Serology, PCR rRNA culture
Lyme disease Borrelia burgdorferi infection	Tick-borne	Intermittent or chronic	Mono- or oligoarthritis, particularly of knees	Erythema migrans, systemic features, ECG disturbances,	Serology

				neurological abnormalities	
Sarcoidosis	F > M	Acute symmetrical Chronic uncommon	Knees, ankles Periarticular involvement	Fever, erythema nodosum and hilar lymphadenopathy (Löffler syndrome)	↑ESR/CRP X-ray lungs bilateral hilar lymphadenopathy
Septic arthritis (non-gonococcal)	Peak incidence in elderly Immuno-compromised state Joint prostheses	Acute, monoarticular, often extremely painful (beware may be polyarticular)	Knee—most common, hip, shoulder, ankle, wrist	Systemic symptoms common	Commonest cause <i>Staphylococcus aureus</i> Synovial fluid is Gram stain positive in 50% and culture positive in 90%
Gonococcal	F > M, young, sexually active	Acute oligoarthritis or polyarthritis	Wrist, knee	Fever, rash, skin blisters/pustules, tenosynovitis	↑ESR/CRP, ↑WBC Synovial fluid Gram stain positive in 25% and culture positive in 50% of cases
Osteoarthritis (OA)	F > M, men with knee or hip involvement ↑Age	Progressive oligoarthritis or polyarticular asymmetrical or symmetrical, bony swelling	DIP, PIP, CMC1, knee, hip, MTP, spine		Normal laboratory tests
Gout	Men, postmenopausal women Diuretic use (especially in elderly)	Sudden onset, severe pain with attacks, oligoarticular early, polyarticular later	MTP, toes, ankle, knees	Tophi	Synovial fluid—urate crystals ↑Uric acid level (normal levels in 40% of acute attacks) RF+ in low titre may be present
Hemochromatosis	M > F 40-60 years	Insidious Symmetric and progressive	Mainly small joints of the hands - MCP II-III Occasionally knees, hips, and shoulders Mild swelling and stiffness	Scin pigmentation, spoon nails, hepatomegaly, liver cirrhosis, diabetes mellitus, hypogonadism, amenorrhea, heart failure Degenerative-like changes in the joints not commonly involved in OA as	Serum ferritin↑ Transferrin saturation↑ ↑LFTs <i>HFE</i> mutations C282Y, H63D

MCP, wrists, elbows,
shoulders

ACA, anticentromere antibody; ACE, angiotensin-converting enzyme; ANA, antinuclear antibody; CCP, cyclic citrullinated peptide; CMC1, first carpometacarpal joint; CRP, C-reactive protein; DIP, distal interphalangeal joint; ESR, erythrocyte sedimentation rate; F, female; HBV, hepatitis B virus; HCV, hepatitis C virus; IBD, inflammatory bowel disease; LFT, liver function test; M, male; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint; PIP, proximal interphalangeal joint; RF, rheumatoid factor; UA, undifferentiated arthritis; WBC, white blood cells; RS3PE, Remitting Seronegative Symmetrical Synovitis with Pitting Oedema.

5.2 Investigations

Most cases of suspected inflammatory arthritis will warrant a complete blood count, inflammatory markers and basic serological tests, including RF, ACPA and antinuclear antibodies, renal and liver function tests and a urine analysis.

The need for more specific tests may be directed by the clinical presentation, including tests for uric acid, cultures where infection is suspected, serology for infections - for example, Lyme disease and virology—for example, hepatitis B, C or B19 parvovirus (IgM antibodies), and specific autoantibodies and genetic markers. If crystal arthropathy or infection is suspected, an aspirate of a joint effusion will be of value in making a definitive diagnosis. Findings on X-ray examinations may further assist in making the diagnosis of a specific arthropathy—for example, the presence of cartilage calcification in calcium pyrophosphate dihydrate deposition disease (figure 5), large asymmetrical erosions with periosteal reaction and late development of ‘pencil in cup’ deformities in psoriatic arthritis, joint space narrowing with sclerosis and hook-like osteophytes of MCP2 and 3 in hereditary haemochromatosis, large asymmetrical erosions with sclerotic rims in gout and space narrowing with subchondral sclerosis and osteophyte formation sparing MCP joints in osteoarthritis.

Figure 5 Calcification of the triangular fibrocartilage of the wrist in calcium pyrophosphate dihydrate deposition disease (CPPD).

6 Prediction of outcome of undifferentiated and early RA

After excluding other diseases and making a diagnosis of probable RA or UA, the third step is to determine which patients are at risk of developing persistent and/or erosive arthritis. This prognostic assessment is important for guiding optimum treatment strategies. Predictors of persistence and disease progression include demographic, genetic, clinical, serological and radiological factors (Landewé, 2007).

6.1 Assessment of disease persistence

The frequent spontaneous remission of synovitis in patients with early arthritis (especially those with symptoms of <3 months' duration) means that a therapeutic approach, which targets all patients with very early synovitis, will expose many patients to unnecessary and potentially toxic treatments. The ability to distinguish resolving disease from synovitis that persists and will develop to RA is thus essential. Female gender, cigarette smoking, duration of symptoms, the tender and swollen joint count, hand involvement, the level of acute phase response, presence of RF and ACPA, and fulfilment of the 1987 ACR diagnostic criteria for RA (sensitivity 88%; specificity 73%) are factors associated with disease persistence (box 1).

Box 1 Candidate predictors of disease persistence in early arthritis

- Female gender
- Duration of symptoms (more than 12 weeks)
- High tender and swollen joint count
- Hand involvement
- Cigarette smoking
- Raised acute phase response
- Positive RF
- Positive ACPA
- Erosions on X-ray examination

ACPA, antibodies to citrullinated peptide; RF, rheumatoid factor.

An alternative approach is to differentiate the patients with arthritis that more likely to enter spontaneous early remission. Sero negativity for RF and fewer active joints at baseline in early RA have been suggested as markers of a favourable outcome (Eberhardt and Fex, 1998).

6.2 Assessment of disease severity

In clinical practice, treatment of early RA should be started as soon as the diagnosis of RA is made, treatment should be aimed at reaching a target of remission or low disease activity as soon as possible in every patients, and treatment should be and adjusted according to the disease activity and other factors such as progression of structural damage, comorbidities and safety concerns.

Many of the factors predicting disease persistence are also markers of disease severity. Joint damage and functional disability are the two most common outcome measures of disease severity.

The most reliable prognostic factors of radiological joint damage are a high acute phase response, the presence and titre of RF and ACPA, the HLA-DRB1*0401 allele subtype and early erosions. Factors that have been found to predict future disability include a baseline Health Assessment Questionnaire (HAQ) score, Ritchie index, erythrocyte sedimentation rate (ESR) and CRP, and presence of erosions. Female gender, older

age, the number of damaged joints, RF positivity and the presence of nodules (although usually a later finding in RA) at baseline are other documented factors (box 2).

Box 2 Candidate predictors of disease severity in early arthritis

- Female gender*
- High tender* and swollen joint† count
- High HAQ score*
- Raised acute phase reactants*†
- Positive RF†
- Positive ACPA†
- Shared epitope†
- Erosive disease*†

**Predictors of functional disability; †predictors of joint damage.*

ACPA, antibodies to citrullinated peptide; HAQ, Health Assessment Questionnaire; RF, rheumatoid factor.

6.3 Individual factors predicting persistence and disease severity

6.3.1 Symptom duration

Several studies have shown longer symptom duration at first visit to be a predictor of disease persistence (Tunn and Bacon, 1993; Schumacher, 2004). In a study by Green et al, 63 patients with mild untreated early inflammatory arthritis were given a single dose of glucocorticoids at presentation. At 6 months, 49 patients (78%) had persistent inflammatory joint disease and 14 (22%) had clinical disease remission. The strongest predictor of persistence was disease duration of >12 weeks (Green et al, 1999). With disease of ≤12 weeks, the chance of remission was increased 5-fold. The 1987 ACR classification criteria for RA were found to be less helpful in predicting persistence in those with shorter disease duration; of those fulfilling the ACR criteria at presentation, 53% with disease duration of ≤12 weeks had persistent disease 6 months later compared with 94% who presented with symptoms >12 weeks.

A further study examined the use of intra-articular glucocorticoid injections in patients with early oligoarthritis (Green et al, 2001). At least 50% of patients in this study had complete response at 2 weeks and the presence or absence of synovitis at 2 weeks predicted response at 12 and 26 weeks. Failure to respond by 2 weeks indicated a high likelihood of further persistent disease and the need for DMARD therapy.

As discussed earlier, symptom duration is also an important predictor of disease severity, with better clinical and radiographic outcomes seen in patients with shorter symptom duration at the first visit to the rheumatologist (Emery et al, 2012; van der Linden et al, 2010).

6.3.2 Early morning stiffness

EMS is an early symptom of an inflammatory arthritis. It is, however, a complex symptom and may be difficult for patients to distinguish from pain and functional limitation. It has been used as a clinical marker of disease

persistence (Visser et al, 2002; van der Helm-van et al, 2007). During the first phase development of the 2010 ACR/EULAR RA classification criteria, EMS—using the traditional cut-off point of 1 h—was not found to be predictive of starting methotrexate in patients with early inflammatory arthritis and was therefore subsequently not included in the final classification criteria (Funovits et al, 2010). This notion has been challenged during subsequent investigations that in the large dataset demonstrated that in patients with arthralgia morning stiffness ≥ 60 min was associated with arthritis, and in the group of patients with early arthritis duration of morning stiffness ≥ 30 min discriminated patients with RA (van Nies et al, 2015).

6.3.3 Joint involvement

In a cohort of 121 patients with early arthritis followed up for a median duration of 5 years, those with polyarticular disease and hand involvement were more likely to have persistent disease (Schumacher et al, 2004). These findings have been confirmed by several other studies (Machold et al, 2002; Sokka et al, 2003). Persistent joint inflammation leads to joint destruction.

6.3.4 Functional disability

Functional disability as measured by the Stanford HAQ disability index is one of the most reliable predictors of disease outcomes in early arthritis (Pincus and Callahan, 1985). A high baseline HAQ is an important risk factor for the development of future functional disability and predictive of both all-cause and cardiovascular mortality in patients with early disease. Analysis of data from a primary care-based inception cohort of patients with recent-onset polyarthritis found that the 1-year HAQ score was a better predictor of subsequent outcome than the baseline HAQ score (Wiles et al, 2000). The baseline HAQ score has been shown to be predictive of quality of life and work disability (Combe et al, 2003; Eberhardt et al, 2007) in patients with early RA.

6.3.5 The acute phase response

A rise in the level of acute phase reactants, such as the ESR and CRP, provides a surrogate measure of inflammation. The combination of ESR and CRP yields useful information that is often not apparent when only a single test is used.

6.3.6 Rheumatoid factor

Historically, RF has been one of the most consistent markers of disease persistence and progression of radiographic damage in patients with inflammatory arthritis (Wolfe et al, 1993; Bukhari et al, 2002; Machold et al, 2007). Further, RF at a high titre was found to be a predictor of disability (Harrison et al, 2000).

6.3.7 Anti-cyclic citrullinated peptide antibodies

Research into autoantibodies other than RF in serum samples of patients with RA led to the discovery of antiperinuclear factor in the 1960s and anti-keratin antibodies in the 1970s. Subsequent studies showed that these antibodies recognised a similar antigen, citrulline. This non-standard amino acid is generated by the post-translational modification of arginine residues by the enzyme peptidylarginine deiminase. Several tests have been developed to identify the antibodies to citrullinated peptides/proteins (ACPA). The assay using the second-generation cyclic citrullinated peptide as an artificial autoantigen (CCP2) is the most commonly used test in clinical practice.

ACPA are present early in the disease course and can precede onset of symptoms by up to 10 years, particularly in the 2 years before symptom onset (Rantapää-Dahlqvist et al, 2003; Berglin et al, 2004). ACPA represents an independent risk factor for developing RA in patients with undifferentiated arthritis or arthralgia. In early UA, 93% of patients who were ACPA (CCP2) positive at baseline were diagnosed with RA at 3 years. Conversely, only 25% ACPA-negative patients had a diagnosis of RA at follow-up (van Gaalen et al, 2004). In patients with arthralgia but without clinical synovitis, an expanded ACPA repertoire recognizing different citrullinated peptides and higher anti-CCP levels (were associated with a higher risk of developing inflammatory arthritis (van de Stadt et al, 2011).

A review of data has shown that ACPA has a similar sensitivity to RF in cohorts with early RA (41–63% vs 41–66%), but a greater specificity (91–100% vs 87–97%). The positive predictive value for ACPA in UA was 78–96% in the cohorts with early RA, and the negative predictive value 62–96% (Aggarwal et al, 2009).

The presence of ACPA has also been shown to independently associate with baseline and long-term disease severity in patients with inflammatory polyarthritis (Farragher et al, 2010) and of radiographic damage and radiographic progression in patients with RA (Meyer et al, 2003). One study has shown a direct association between ACPA, osteoclastogenesis and serum markers for osteoclast-mediated bone resorption in patients with RA (Harre et al, 2010). ACPA titres have also been related to disease severity (Berglin et al, 2006) but measuring ACPA titres has not been proved to be of value in monitoring treatment outcomes. A subanalysis of the CARDERA (Combination Anti-Rheumatic Drugs in Early RA) trial has evaluated the usage of ACPA in guiding treatment decisions. In this study patients who were ACPA-positive had less radiographic progression when treated with combination DMARD therapy or when treatment included an initial high dose of oral glucocorticoids. ACPA-negative patients, as expected, had minimal radiographic progression irrespective of treatment (Seegobin et al, 2014).

However, the recent subanalysis of the Dutch dynamic treatment strategy study, the BeST-trial, pointed out that treatment of all patients with early and active RA should focus on rapid relief of symptoms, and there is no reason to weigh the initial treatment choice based on the presence of autoantibodies. In this analysis,

ACPA-negative and RF-negative patients also benefited from initial combination therapy, with a better functional ability at 3 and 6 months follow-up compared to patients treated with initial methotrexate monotherapy (Akdemir et al, 2016).

6.3.8 Other autoantibodies and immune markers

Despite the diagnostic value of ACPA and RF, the disease in a proportion of patients with inflammatory arthritis will still be classified as seronegative RA. Research has led to the finding of several other autoantibodies, antibodies to carbamylated antigens (anti-CarP) are ones of these new autoantibodies (Trouw and Mahler, 2012). These autoantibodies recognise carbamylated but no citrullinated protein antigens. IgG anti-CarP and IgA anti-CarP antibodies have been described in 16% and 30% of ACPA-negative individuals with inflammatory arthritis, respectively (Shi et al, 2011). Anti-CarP antibodies have been found in both ACPA-negative and ACPA-positive patients with RA and also in preclinical phase of the RA-disease. In patients positive for CarP and negative for ACPA, more severe erosive course of disease has been reported (Shi et al, 2011). Already in the pre-symptomatic ACPA-negative individuals the presence of anti-CarP antibodies has been shown to associate with RA development (Brink et al, 2015). In the recent analysis in early RA, anti-CarP antibodies were associated with more radiographic progression in the ACPA-positive/RF-negative, ACPA-negative/RF-positive and ACPA-positive/RF-positive patients, but with known ACPA and RF status the anti-CarP antibodies did not improve correct classification of patients with progressive joint damage disease (Ajeganova et al, 2016).

In addition to autoantibodies, levels of cytokines and chemokines, including interleukin (IL)-1 α , IL-1 β , IL-6, IL-10 and tumour necrosis factor α (TNF α), have been found to be elevated in the preclinical period of RA development, with increasing numbers of cytokines/chemokines predictive of decreased time to diagnosis (Deane et al, 2010).

6.3.9 Genetic markers

The shared epitope (SE), a group of HLA-DRB1 alleles that share a similar amino acid sequence, is strongly associated with RA. Among the different HLA-DRB1 alleles examined, HLA-DRB1*401 and DRB1*0404 have been consistently associated with radiographic erosions in different ethnic groups. This association appears to be dose dependent as patients with two RA-associated alleles (DRB1*04 or DRB1*01) have more radiographic erosions and more joint replacement than patients with non-disease-associated alleles (Weyand et al, 1992). Studies have shown that individuals who were homozygous for HLA-DRB1*0404 were four times more likely to develop erosions than those who were SE negative (Harrison et al, 1999; Goronzy et al, 2004).

Since ACPA tests have been included in multivariate analyses, however, HLA-DRB1 genes have no longer been shown to be independent predictive factors of severity in RA. In most populations, their effect is accounted for

by the presence of ACPA. (Further discussion on the association with the SE and smoking and the development of ACPA can be found in chapter 9, Rheumatoid Arthritis: Pathogenesis and Clinical Features.)

A number of other genetic polymorphisms have been studied in patients with early RA. We refer for an in-depth discussion to the chapter on genetics in this EULAR Textbook.

Although discovery of specific genetic risk factors (in particular, SE) has been essential in our understanding of RA pathogenesis, testing for these markers is not recommended in routine clinical practice.

6.3.10 Smoking

Smoking is the most recognised environmental risk factor for the development of RA. There is also a strong association between smoking and increased occurrence of extra-articular manifestations, including rheumatoid nodules, in early seropositive RA.

Studies have gained insights into the potential role of smoking in the pathogenesis of RA. It has been shown to increase the risk of developing ACPA. In the presence of HLA-DRB1 SE alleles, this risk is further increased—up to 20 times in homozygotes as compared with SE-negative non-smokers in ACPA-positive persons (Klareskog et al, 2006; Klareskog et al, 2007). It suggests that smoking in a genetically predisposed individual triggers apoptosis and protein citrullination, followed by an anti-citrulline-specific immune response. Former smokers are also at an increased risk for RA up to 20 years after stopping smoking, with a gradually decreasing risk over time (Heliovaara et al, 1993).

Outcomes of studies assessing the effect of smoking on disease severity vary, however. Several cross-sectional studies have demonstrated significant associations between smoking and more radiographic damage progression (Saag et al, 1997; Masdottir et al, 2000), while other studies, including a large observational study of 2004 patients with RA (Finckh et al, 2007), have found no difference in rates of radiographic progression between current or previous smokers and non-smokers (Harrison et al, 2001; Forslind et al, 2004). The large multi-centre study indicated that effect of smoking on joint damage is mediated via ACPA and that smoking is not an independent risk factor for radiological progression in RA (de Rooy et al, 2014). In the population-based early RA cohort, current cigarette smokers have been shown to respond less likely to methotrexate and TNF inhibitors (Saevarsdottir et al, 2011). The decreased chance of response associated with current smoking was observed for a good response and remission according to the EULAR criteria, and for the DAS28 scores and the joint counts at follow-up. In this study, the influence of smoking did not differ significantly between ACPA-positive and ACPA-negative patients.

6.3.11 Imaging

6.3.11.1 Conventional radiographs

X-ray examinations are the conventional imaging modality. Radiographic erosions have a high specificity in discriminating between self-limiting and persistent arthritis (Visser et al, 2002). Early radiographic changes are also predictive of disease progression. In a cohort of 518 patients with UA the presence of two or more erosive joints at baseline showed a positive predictive value for RA development of 53% and for persistent disease of 68% (Thabet et al, 2009). Patients with erosions that did not develop RA were less often ACPA-positive, RF-positive and had lower CRP/ESR and number of swollen joints compared to those who developed RA. Feet erosions were equally predictive compared to erosions at hands in this study.

Radiographic examination should include assessment of the hands and feet as erosions often start in the feet and in about 14–18% of cases are only detected in the feet (figure 6) (Fex et al, 1996). In general, anteroposterior views are used. Other views—for example, lateral or oblique views, may be requested if clinically indicated.

Figure 6 Conventional radiograph of the foot showing erosions of the fifth metatarsal head.

Radiographic damage at baseline is also the best predictive factor of poor structural outcome. Irrespective of the scoring systems (eg, van der Heijde Sharp score (SHS) and Larsen score) used, the initial radiographic score consistently predicts future radiographic damage (Jansen et al, 2001).

Joint erosions and joint space narrowing seen on X-ray examinations, however, are generally late findings. Newer imaging modalities have been shown to provide additional diagnostic information at an earlier stage.

6.3.11.2 Magnetic resonance imaging

Magnetic resonance imaging (MRI) can assess all structures of the inflamed joint. It is more sensitive than clinical examination and radiography for the detection of synovitis and erosions in early RA. There is also evidence that MRI findings (synovitis, bone oedema and bone erosions) may predict subsequent radiographic progression. Changes resembling mild synovitis or small bone erosions, however, are occasionally found in the joints of healthy subjects. The newly published review of the literature on 31 MRI studies assessed the occurrence of MRI features in symptom-free persons (Mangnus et al, 2015). The MRI erosions were present in 33-52% of symptom-free persons, synovitis in 27% and bone oedema in 0-16%. The prevalence of MRI-detected erosions was shown to increase with age. Higher costs, longer examination times and lower availability are some disadvantages of MRI compared with conventional radiographs. The role of MRI of joints in clinical practice is to be established.

6.3.11.3 Musculoskeletal ultrasonography

The use of MSUS for the management of patients with early arthritis has increased over the years. It is useful for detecting synovitis in small joints of the hands and feet with greater sensitivity than clinical examination. It is also more sensitive for visualising synovitis and bone erosions in the finger joints than conventional X-ray examinations (figure 7). The advantages of US are that it is relatively inexpensive, non-invasive and allows assessment of many joints. The main disadvantage is its dependency on the skills of the operator and problems with reproducibility.

In patients without clinical synovitis, the role of ultrasound is not clear. One of the studies encouragingly reported prediction of development of inflammatory arthritis in patients with seropositive new-onset arthralgia, based on MSUS findings (grey scale, power Doppler signal and erosions) (Rakieh et al, 2015; Nam et al, 2016). However, it should be noted that MSUS findings are quite common in healthy persons and were reported in 88% of healthy persons without joint symptoms (Padovano et al, 2015). It is of importance to interpret MSUS imaging cautiously and always in the context of clinical situation. In patients with RA, MSUS findings in active both large and small joints reflect synovial histological scores, DAS28 and CRP (Abe et al, 2016).

So far it is not proved that including ultrasound examination leads to better outcomes for patients with early RA (Dale et al, 2016; D'Agostino et al, 2016). The level of agreement and impact on treatment decision-making of adding MSUS to clinical assessment of disease activity in early RA patients has been assessed in the TSERA study (Targeting Synovitis in Early Rheumatoid Arthritis study) (Dale et al, 2014). MSUS power Doppler was performed in 14 joints on patients with low disease activity ($\text{DAS28} < 3.2$) and with moderate disease activity ($3.2 \leq \text{DAS28} < 5.1$) without clinically swollen joints. Data from 414 paired DAS28 and MSUS assessments were pooled to determine the level of agreement between each method. MSUS identified persistent disease activity in a quarter of patients with low disease activity or clinical remission; on the other hand, MSUS confirmed active disease only in one-third of patients with moderate disease activity. In 29% of assessments MSUS findings contradicted the DAS28 and led to modified therapeutic decisions. The authors conclude that compared to the DAS28, global RA disease activity assessment using a limited MSUS joint set provided additional disease activity information and led to altered treatment decisions in a significant minority of occasions. In the real-life cohort of patients with RA followed for 3-5 years, 'the silent radiographic progression' in an individual joint without any clinical activity in any other joint has been reported to be very rare, 5.8% of the patients, suggesting that remission assessed clinically is a marker of structural stability (Gärtner et al, 2016).

Figure 7 Imaging of the second metacarpophalangeal joint of a patient with rheumatoid arthritis. (A) Conventional radiography shows juxta-articular osteoporosis. (B) Ultrasonographic examination, in the longitudinal dorsal scan, shows proliferative synovitis with marked intra-articular power Doppler signal. m, metacarpal bone; p, proximal phalanx; t, extensor tendon.

Mostly, MSUS imaging is currently used for disease monitoring as a part of clinical investigation. Whether combination of clinical, serological and imaging (ultrasound) findings could potentially help for more precise treatment decisions in individual patients with early arthritis is to be defined.

6.3.12 Hand bone densitometry

With newer treatments for RA, erosion progression is lower, requiring more sensitive measures to assess treatment outcomes. In RA, bone loss, particularly in the hands, takes place early in the disease process. Measuring hand bone loss may therefore be useful for diagnosis and as a marker of disease activity. Dual energy X-ray absorptiometry (DEXA) measures bone density with high precision, making it sufficiently sensitive to detect even small changes in bone mass. Studies in RA assessing bone mineral density (BMD) have shown a good correlation between BMD loss in the spine (Gough et al, 1994) and hand (Devlin et al, 1996) with disease activity. DEXA has been found to be a more sensitive tool than radiology for measuring disease-related bone damage. Of 58 patients with early RA of <12 months' duration, 50% showed significant individual BMD hand bone loss after 24 weeks compared with only 22% showing the smallest detectable radiographic progress evaluated by SHS method at 48 weeks (Haugeberg et al, 2007). In early arthritis patients without baseline erosions, early metacarpal BMD loss after 4 months is reported as the main predictor of radiological progression after 1 year (Wevers-de Boer et al, 2015). Change in BMD hand bone loss at one year is correlated significantly and inversely with the change in SHS at two, five and eight years, and only change in SHS during the first year and the presence of ACPA has been reported as independent predictors of long-term progressive joint damage in early RA (Forslind et al, 2012).

6.3.13 Histology

Studies using arthroscopy have confirmed imaging findings of subclinical synovitis examining asymptomatic joints of newly diagnosed RA. Distinct macroscopic vascular patterns have been seen in early RA and psoriatic arthritis (figure 8). Comparison of histopathological features of synovial tissue in early RA and non-RA synovitis has shown subtle differences in histological features, cytokine and protease expression patterns, as well as apoptosis. An analysis of synovial biopsies of 95 patients with early arthritis showed that the higher scores for the number of CD38+ plasma cells and CD22+ B cells were the best markers for distinguishing between patients with and without RA. The number of CD68+ macrophages in the synovial tissue of patients with RA was also increased (Kraan et al, 1999). Thus far, however, the clinical value of the histopathological characteristics of synovial tissue in early arthritis has not yet been proved (Hitchon and el-Gabalawy, 2003). Widespread use of synovial biopsies in the clinical setting is also limited by its invasiveness.

Figure 8 Arthroscopy showing rheumatoid synovitis. Hypertrophic, rounded, polypoid-like villi with an opaque, ill-defined background due to congestion and oedema.

6.3.14 Biomarkers of joint destruction

Molecular markers that reflect synovial, bone and cartilage turnover have been studied as potential tools for early identification of patients with RA at high risk of rapid disease progression (Landewé, 2007). These include urinary glucosyl-galactosyl-pyridinoline, a marker of destruction of the synovium, and C-terminal crosslinking telopeptides of type I and type II collagen (CTX-I and CTX-II), markers of bone and cartilage destruction. High baseline levels of CTX-I and CTX-II have been shown to (weakly) associate with radiographic progression.

Raised levels of matrix metalloproteinases, enzymes involved in the degradation of articular cartilage in RA, have been found in tissue, synovial fluid and the systemic circulation of patients with RA. Several studies have shown a correlation between increased matrix metalloproteinase levels and progression of joint damage.

The osteoprotegerin:nuclear factor (NF) kappaB ligand (OPG:RANKL) ratio may be another marker of joint destruction, with low levels predictive of more rapid progression. Osteoclasts play a key role in the mechanism of joint destruction in RA. RANKL and its receptor RANK are central to the stimulation of osteoclast formation and activation, and the soluble receptor-like molecule OPG is a natural inhibitor of RANKL. Bone resorption is regulated by the balance between RANKL and OPG.

High levels of calprotectin (myeloid-related protein 8/14, expressed in granulocytes and monocytes) in plasma/serum and/or synovial fluid have been shown to predict erosive joint damage progression and therapeutic responses (Abildtrup et al, 2015).

However, analysis of cartilage and bone biomarkers is not more useful than current predictors of clinical and radiographic outcomes in RA—for example, ACPA and the presence of early radiographic damage. In daily clinical practice, the role of these biomarkers is not demonstrated.

6.4 Phases up to the development of RA

Research at the very earliest stages of RA has led to the formation of a ‘Study Group for Risk Factors for RA’ (Gerlag et al, 2012*). The group has published recommended terminology to define the specific phases up to the development of RA in order to phenotype/characterize these phases and to standardize further research in the field (box 3). These phenotypes include certain genetic profiles (eg, SE), environmental factors (eg, smoking) and autoantibodies (eg, RF and ACPA) - known risk factors for the development of RA.

Box 3 Recommendation for terminology to be used to define specific phases up to the development of rheumatoid arthritis (RA)

In prospective studies individuals would be described as having:

1. Genetic risk factors for RA
2. Environmental risk factors for RA
3. Systemic autoimmunity associated with RA
4. Symptoms without clinical arthritis
5. Unclassified arthritis
6. RA

The term ‘arthritis’ is used to denote clinically apparent soft tissue swelling or fluid (not bony overgrowth alone).

(a) to (e) can be combined—for example, an individual may have (a)+(b), or (a)+(b)+(c) or (a)+(b)+(d), etc. The prefix ‘pre-RA with:’ can be used before any/any combination of (a) to (e) but only to describe retrospectively a phase an individual was in once it is known that they have developed RA.

Reproduced from Gerlag et al, Ann Rheum Dis 2012;71:638–41.

6.5 Predictors of persistence and disease severity: practical points

In practice, the clinical features and investigations listed in boxes 1 and 2 may be used to identify patients with early inflammatory arthritis who are at risk of a persistent and more severe disease course. X-ray of hands and feet is the mainstay imaging modality, although the use of MSUS, MRI and DEXA is coming to the fore. Non-HLA genetic markers, histology and biochemical markers remain more research-based tools rather than investigations for day-to-day patient care.

Development of the 2010 ACR/EULAR classification criteria has been an important step forward, setting a new benchmark for the early identification of patients with RA - aiming to start effective treatment as early as diagnosis is made, thus preventing the adverse sequelae of the disease. Currently great efforts are being made

with focus on identification of clinical, serological, genetic factors, MSUS and MRI imaging features aiming to predict the development of inflammatory arthritis in individuals at risk (van de Stadt et al, 2012; Rakieh et al, 2014, van Steenbergen et al, 2015).

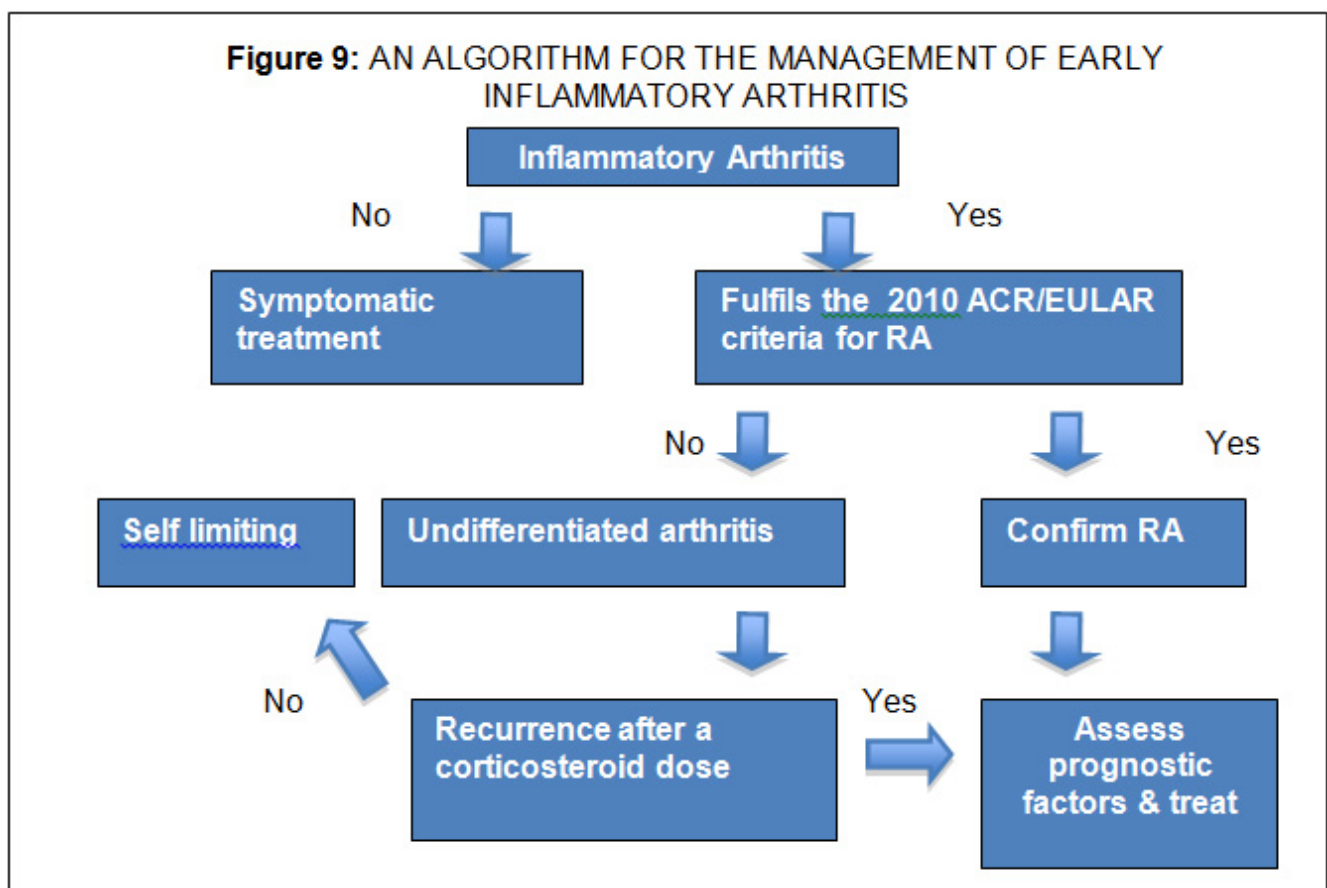

7 Treatment

Patients with early arthritis will require a combination of pharmacological and non-pharmacological treatment.

- The first principle of pharmacological treatment for early arthritis is early effective intervention.
- The second principle is treating to target - T2T (Smolen et al, 2010*) to achieve 'tight control' of disease activity. In practice, this means monitoring of disease activity and adjusting/adapting treatment as long as the target of predefined disease activity (ideally remission) has not been reached.

A suggested algorithm for the management of early arthritis is shown in figure 9.

Figure 9 An algorithm for the management of early inflammatory arthritis.

7.1 Non-pharmacological treatment and lifestyle measures

As discussed earlier in this review, smoking increases the risk of developing RA, affects progression of the disease and is associated with more joint damage progression, extra-articular manifestations and may reduce

the efficacy of anti-rheumatic therapies. Obesity in patients with early RA is associated with higher disease activity and HAQ score, more pain, worse general health, lower chance for sustained remission and higher prevalence of comorbidities (Ajeganova et al, 2013).

Though it is currently unclear whether smoking cessation and weight reduction may improve RA outcomes, apart from lowering cardiovascular risks, both factors do have an effect on response to treatment and various disease outcome measures, which justify efforts aimed at cessation of smoking and weight reduction in obese patients. Regular physical activity may also benefit patients with RA. Several non-pharmaceutical interventions—such as dynamic exercises, occupational therapy and hydrotherapy—have shown beneficial symptom-relieving effects in established RA. These are recommended as adjuncts to pharmaceutical interventions in patients with early arthritis.

7.2 Patient education

As part of the management of any chronic disease, patients should be provided with information about the disease and its treatment. Education programs may be used as adjunctive measures, aimed at coping with pain and disability and the maintenance of work ability.

Patients with an inflammatory arthritis who do not meet criteria for a specific diagnosis and do not have poor prognostic factors are much more likely to do well. About 15-50% of patients with very early undifferentiated arthritis, often those with arthritis after a transient viral infection, may be found in spontaneous remission at follow-up. Although patients may feel disappointed when a specific diagnosis is lacking, they may be reassured of a better outcome.

7.3 Pharmacological treatment

7.3.1 Symptomatic treatment

Analgesics may be required for pain management in early RA. These are often used in combination with treatments to control the inflammatory process. Both classical non-selective cyclooxygenase (COX) inhibitors and COX 2-selective non-steroidal anti-inflammatory drugs (NSAIDs) are more effective than analgesics in relief of signs and symptoms of active RA disease. At full dosages all NSAIDs are potentially equally effective; however, there is a great variation in tolerance and response to a particular NSAID. The major effect of NSAID is to reduce acute inflammation thereby decreasing pain and improving function. All of NSAIDs also have mild to moderate analgesic properties independent of their anti-inflammatory effect. NSAIDs could be considered in symptomatic patients after evaluation of gastrointestinal, renal and cardiovascular risk (further discussion may be found in chapter 10, Rheumatoid Arthritis: Treatment). It is important to note that these drugs alone do not change the course of RA-disease and do not prevent joint destruction.

7.3.2 Glucocorticoids

Glucocorticoids (GCs) have anti-inflammatory and immunosuppressive effects and are widely used for the treatment of RA (Gorter et al, 2010).

An approach for patients who present with very early undifferentiated inflammatory arthritis (<12 weeks of symptoms) is a single dose of GCs administered by either intramuscular or intraarticular injection for rapid improvement of symptoms with following assessment to evaluate persistency of synovitis or its resolution (Green et al, 2001).

Two randomised placebo-controlled studies have also investigated the benefits of a limited course of intramuscular (IM) steroids in patients with early UA. The STeroids In Very Early Arthritis' (STIVEA) trial (Verstappen et al, 2010) aimed to determine whether treatment of recent-onset inflammatory polyarthritis with three weekly injections of IM GCs could suppress evolution to RA. In this trial, 265 patients with 4–11 weeks of symptoms, ≥ 2 tender and swollen joints and hand involvement were enrolled and randomised to receive three weekly doses of methylprednisolone 80 mg IM or placebo. At 6 months, 76% of the placebo group and 61% of the steroid group had either started or been referred for DMARD therapy (OR = 2.11, $p = 0.015$). At 12 months, the arthritis had resolved in 20% of patients in the glucocorticoid arm compared with 10% in the placebo arm. However, in the Stop Arthritis Very Early (SAVE) study (Machold et al, 2010), a single dose of IM methylprednisolone 120 mg was not effective. As expected, significantly more patients with polyarthritis than with oligoarthritis received DMARDs in this study (OR = 2.84, $p < 0.0001$). The use of a single injection and longer symptom duration (≤ 16 weeks) at inclusion may have resulted in the fact that delay in development of RA was not found. However, at this point, the use of IM steroids in some patients with very early inflammatory polyarthritis is supposed to postpone the initiation of DMARD therapy.

Several randomized controlled trials and systematic reviews (Gotzsche et al, 2004; Gorter et al, 2010; Gaujoux-Viala et al, 2014) have provided good evidence for the beneficial effects of GCs in early RA. Studies have also shown that GCs in combination with DMARDs retard the progression of erosive disease (Boers et al, 1997; van Everdingen et al, 2002; Korpela et al, 2004; Kirwan et al, 2007; Gorter et al, 2010; Nam et al, 2014b). GCs have also been effectively used as part of tight control treatment strategy studies (Goekoop-Ruiterman et al, 2005; Bakker et al, 2012; de Jong et al, 2014; Heimans et al, 2014; Nam et al, 2014b) (a concept which will be discussed later in this module). According to the current recommendations, GCs in low-to-moderately high doses added to synthetic DMARD provide benefit as initial short-term treatment strategy, but should be tapered as rapidly as clinically feasible (Smolen et al, 2014*).

Concerns are often raised about possible side effects of glucocorticoids. Evidence suggests that side effects depend on the dose used and the disease being treated. A review of the published reports and safety data from RCTs in RA suggests that adverse effects associated with GCs treatment are modest and often not

statistically different from those of placebo (Da Silva et al, 2006). The side effects known to occur in other diseases treated with higher doses of glucocorticoids, such as cardiovascular risk, lipid abnormalities and osteoporosis, may not occur when low-dose GCs are used to treat RA. The EULAR recommendations on the use of GCs in rheumatic diseases effectively and with acceptable safety have been newly published (Strehl et al, 2016). The level of harm of GCs depends on both dose and patient-specific parameters. At dosages between >5 and ≤ 10 mg/day, patient-specific characteristics (protective factors such as a healthy lifestyle, inflammatory control and risk factors) determine the actual and future risk of harm.

7.3.3 Conventional synthetic disease-modifying antirheumatic drugs

Early treatment with disease-modifying drugs (DMARDs) is one of the key principles in the treatment of early arthritis (Gaujoux-Viala et al, 2010). Patients with inflammatory arthritis at risk of developing persistent and/or erosive arthritis should start treatment with DMARDs as early as possible.

There is good evidence that patients with recent-onset polyarthritis who receive earlier DMARD treatment have better outcomes for radiographic progression and function than those in whom DMARD treatment is delayed by a few months (Nell et al, 2004). Disease duration at the time of conventional synthetic DMARD initiation was shown to be the main predictor of response to treatment in the meta-analysis of 14 RCTs by Anderson et al. The best response was seen in those who had had symptoms for <1 year at the start of treatment (Anderson et al, 2000). Another meta-analysis of 12 studies examined the effect of early conventional synthetic DMARD therapy on the long-term radiographic progression in patients with early RA (<2 years at presentation). Six were open-label extensions of RCTs in which placebo patients later started conventional synthetic DMARD therapy and six were observational cohort studies. The average delay between early and late treatment was 9 months. After a median of 3 years of observation, those patients who had received early treatment had 33% less radiological progression than those with delayed treatment (Finckh et al, 2006).

Conventional synthetic DMARDs have an effect on the disease process within weeks to months. Methotrexate, sulfasalazine and leflunomide are commonly used DMARDs, which have been shown to improve clinical outcomes and delay radiological progression. (Details of these drugs can be found in chapter 10, Rheumatoid Arthritis: Treatment.) Of the conventional synthetic DMARDs, methotrexate (MTX) is considered the anchor drug and is generally used first in patients at risk of developing persistent disease or erosive disease because of its favourable long-term safety profile, clinical and radiological efficacy, and its beneficial properties in treatment combinations with biological DMARDs. Leflunomide and sulfasalazine have similar clinical efficacy and are considered the best alternatives.

Despite early treatment, substantial structural damage may still occur in some patients with early RA treated with synthetic DMARDs alone (Machold et al, 2007; Rezaei et al, 2012). In a cohort of patients with very early RA with symptom duration of <3 months, 64% had developed erosive disease by 3 years.

Earlier use of conventional synthetic DMARD therapy—in patients with UA, before the stage of fulfilling ACR criteria for RA—was first examined in the PRObable rheumatoid arthritis: Methotrexate versus Placebo Treatment (PROMPT) study. In this double-blind RCT, 110 patients were randomised to treatment with MTX or placebo for 12 months. In 40% (22/55) of patients in the MTX group the disease progressed to RA compared with 53% (29/55) in the placebo group. In the MTX group patients also fulfilled the ACR criteria for RA at a later time point than in the placebo group ($p = 0.04$), and fewer patients showed radiographic progression over 18 months ($p = 0.046$). This study suggests that MTX may delay the development of RA and retard radiographic joint damage in patients with UA. Further analysis and long-term follow-up showed that these findings were mainly seen in the subgroup of patients who demonstrated the presence of ACPA (van Dongen et al, 2007; van Aken et al, 2014).

7.3.4 Conventional synthetic DMARD (csDMARD) monotherapy versus combination therapy

Several studies have investigated whether initial combination therapy of early RA is more beneficial than conservative strategies. In the COBRA trial, a combination of methotrexate (7.5 mg weekly), sulfasalazine (2 g/day) and prednisolone (starting with 60 mg/day and tapering over 6 months) had long-term beneficial effects on radiographic progression, compared with sulfasalazine monotherapy in 155 patients with RA of duration of <2 years (Boers et al, 1997; Landewé et al, 2002). These results were consistent with those from the FIN-RACo study, in which 197 patients with onset of RA within 2 years were randomly assigned to receive either a four-drug regimen, with methotrexate, sulfasalazine, hydroxychloroquine and prednisolone (maximum doses: 15 mg/week, 2 g/day, 300 mg/day and 10 mg/day, respectively) or a single DMARD (Mottonen et al, 1999; Korpela et al, 2004; Puolakka et al, 2004) for 2 years. After 18 months, a greater proportion of the combination therapy group was less likely to have radiographic progression, and the work disability rate was lower than for patients receiving monotherapy. Although in the latter study, steroid was permitted in the single-treatment group, this was introduced later, at up to 93 weeks from baseline. The effects achieved in the combination treatment arms may therefore be attributed, at least in part, to the use of steroids.

Other trials comparing the MTX/sulfasalazine combination versus single agents (Haagsma et al, 1997; Dougados et al, 1999) were unable to identify better outcomes for any treatment arm over the other. Results from the Behandel Strategieën (BeSt) study showed that after a failure of MTX 25 mg/week, adding sulfasalazine to MTX resulted in Disease Activity Score (DAS) of ≤ 2.4 in only 22% of patients. An equally low response was obtained when switching from methotrexate to sulfasalazine (van der Kooij et al, 2007).

Two recent RCTs have compared efficacy of MTX monotherapy and MTX in combination with other conventional synthetic DMARDs in early arthritis. In the single-blind Treatment in the Rotterdam Early Arthritis Cohort study (tREACH) study, 281 patients with recent-onset inflammatory arthritis at high risk of progression to persistent arthritis (Visser et al, 2002) were randomised to one of three arms: (A) combination csDMARD therapy (MTX, sulfasalazine and hydroxychloroquine) + IM glucocorticoids; (B) combination csDMARDs + oral GCs tapering scheme and (C) MTX monotherapy + oral GCs tapering (de Jong et al, 2013; de Jong et al, 2014). The area under the curve (AUC) of DAS and HAQ was lower in patients receiving combination csDMARDs than in those receiving MTX mainly owing to early treatment effects. At 3 months, disease activity was significantly lower with triple csDMARD therapy. However, at 1 year there was no significant difference in disease activity between the groups; mean (SD) DAS 1.4 (0.68) vs 1.41 (0.87) vs 1.68 (0.89) in arms A, B and C, respectively. Radiographic progression after 1 year was not different between the arms, 21%, 24% and 23% in arms A, B and C, respectively. There were fewer treatment intensifications but more drug changes due to adverse events in the combination therapy group. Both GC bridging therapies were equally effective and, therefore, both can be used in clinical practice.

The Treatment of Early Aggressive Rheumatoid Arthritis (TEAR) study (Moreland et al, 2012; O'Dell et al, 2013), a double-blind RCT, validated the strategy of starting with MTX monotherapy or whether it is better to intensively treat all patients with early poor prognosis RA using combinations of drugs or to reserve this approach for patients who do not have an appropriate response to MTX monotherapy. This trial also assessed whether combination therapy with MTX + etanercept is superior to the combination of MTX + sulfasalazine (SSZ) + hydroxychloroquine (HCQ). The patients were randomized to 1 of 4 treatment arms: immediate treatment with MTX+etanercept, immediate oral triple therapy MTX+SSZ+HCQ, or step-up from MTX monotherapy to one of the combination therapies MTX+etanercept or MTX+SSZ+HCQ at week 24 if the DAS28-ESR was ≥ 3.2 . Remission was achieved earlier with initial combination therapy. However, the primary end-point, DAS28-ESR from week 48 to week 102, and DAS28-ESR remission at week 102 were similar between groups. Thus, the initial MTX monotherapy with the option to step-up to combination therapy resulted in similar outcomes to immediate combination therapy. Approximately 30% of patients in the initial MTX group achieved low levels of disease activity and did not need step-up combination therapy, and the 70% who needed it were clinically and radiographically indistinguishable from those who were randomized to receive immediate combination therapy. The results for either of the immediate combination approaches, whether triple therapy or MTX+etanercept, were also similar. It has been suggested that confounding by low recruitment (and therefore insufficient power) and other factors need to be considered in this trial and that perhaps more significant between-group differences might have been seen if this was not the case (Fleischmann et al, 2013).

In clinical practice, the rationale for the first line treatment in early RA has been investigated in the ESPOIR early arthritis cohort. In all, 370 patients receiving MTX or leflunomide for ≥ 3 months within the first year of follow-up were clinically assessed every 6 months. Presence of RF or ACPA and initial structural damage, but not DAS28 or CRP, were predictive of rapid radiographic progression at 1 year (Granger et al, 2016). This result supports the viewpoint that the early induction of remission may change the course of RA-disease.

Based on review of the published data, (Gaujoux-Viala et al, 2010; Gaujoux-Viala et al, 2014) EULAR recommendations for the management of RA have suggest that in DMARD-naïve patients, irrespective of the addition of GCs, synthetic DMARD monotherapy rather than combination therapy may be applied with following tight control and monitoring of therapy response. Where disease control is not achieved with the first line DMARD, switching to an alternative DMARD strategy should be considered in the absence of poor prognostic factors, while addition of a biological DMARD should be considered when poor prognostic factors are present (Smolen et al, 2014*).

7.3.5 Biological DMARD therapy

There is strong evidence in favour of traditional synthetic DMARDs combined with a remission induction scheme of glucocorticoids to achieve adequate efficacy in controlling early RA with good safety and feasibility in daily clinical practice. However, an alternative approach to treating DMARD-naïve patients with early arthritis is to target the subgroup of patients with moderate-to-severe, active, progressive RA and poor prognostic markers with a biological agent in combination with MTX.

Several RCTs in patients with early RA have shown an increased rate of inducing and sustaining clinical remission, improved physical function and slowing of radiographic progression with a TNF inhibitor in combination with MTX, compared with MTX monotherapy (Genovese et al, 2002; St Clair et al, 2004; Quinn et al, 2005; Breedveld et al, 2006; van der Heijde et al, 2010; Smolen et al, 2011; Kavanaugh et al, 2013; Emery et al, 2016). In patients offered early combination therapy, it has been shown dissociation between clinical and structural outcomes when even in cases in which clinical activity was not optimally suppressed, radiographic progression appeared to be significantly retarded (Smolen et al, 2005).

In the Combination of Methotrexate and etanercept study (COMET) (Emery et al, 2008), the first major study looking at remission as the primary endpoint in patients with early RA, patients with symptom duration of ≤ 2 years were randomized to receive MTX or MTX and etanercept for a year. At week 52, remission defined as DAS28 < 2.6 , was achieved in 50% of patients receiving etanercept + MTX vs 28% of patients receiving MTX alone ($p < 0.001$) (figure 10). Regardless of disease duration, no radiographic progression was seen in 80% of patients with etanercept + MTX. In contrast, a higher proportion of very early RA (≤ 4 months symptom duration) showed no radiographic progression compared with early RA (> 4 months and < 2 years) patients

treated with MTX (74% vs 50%) (Emery et al, 2012). This suggests that early suppression of disease activity is important to prevent damage in early arthritis and could be reached with a conventional DMARD as MTX.

Figure 10 Percentage of patients achieving 28-joint count Disease Activity Score (DAS28) remission (primary endpoint) and DAS remission at week 52 in the groups receiving methotrexate (MTX) versus MTX plus etanercept (ETN). (Reproduced with permission from Emery et al, Lancet 2008;372:375–82.)

During the second year, patients in the MTX group were randomised to receive MTX (M/M) alone or MTX + etanercept (M/EM) and those in the MTX + etanercept group to continue with combination therapy (EM/EM) or to receive etanercept alone (EM/E). At year 2 clinical outcomes were better in the groups that received etanercept compared with the group receiving MTX alone. DAS28 remission was achieved in 62/108 (57%) and 51/88 (58%) of the EM/EM and M/EM groups, which was significantly greater than that in the M/M group 35%, ($p<0.05$, but not significantly greater than that in the EM/E group, 50%). Radiographic progression was also lower in those patients who received etanercept with the lowest rate of progression seen in the groups treated with etanercept early (figure 11) (Emery et al, 2010c).

Similar radiographic benefits have been shown in other RCTs in patients with early arthritis receiving non-anti-TNF biologic DMARDs (Nam et al, 2014a; Smolen et al, 2015). A double-blind, placebo-controlled study of abatacept in patients with ACPA-positive UA/very early RA (not fulfilling ACR criteria for RA), suggests that in some patients it is possible to change the natural history of the disease and alter the progression of RA by modulating T-cell responses at a very early stage of disease. In this study the patients were randomised to abatacept or placebo for 6 months (Emery et al, 2010b). Delayed progression to RA (by ACR criteria) at 1 year was found in the abatacept group, thus, 46% abatacept-treated versus 67% placebo-group patients developed

RA. A favourable effect was also shown on radiographic and MRI inhibition in the abatacept group. Of note, use of DMARDs and biological agents in patients with early undifferentiated disease is not established but is an area of growing research.

Figure 11 Radiographic progression over 2 years. Mean changes in modified Sharp/van der Heijde total score (mTSS) from week 0 to week 104, based on the last observation carried forward analysis. ETN, etanercept; MTX, methotrexate. *One subject did not have a valid radiograph at week 52 but did at baseline and week 106; changes from week 52 to week 104 cannot be assessed. (Reproduced with permission from Emery et al, *Arthritis Rheum* 2010;62:674–82.)

The biologic DMARDs provide rapid control of inflammation and have proven efficacy on clinical outcomes and structural damage in early disease. They are, however, substantially more expensive than traditional DMARDs (Schoels et al, 2010b). Selecting patients with poor prognostic factors and tapering a biologic agent when the patient is in stable remission may improve this cost–benefit balance. So far there is no convincing evidence that very early treatment with first-line biologics increases the proportion of patients with early arthritis achieving clinical remission and drug-free remission in comparison to treat-to-target conventional therapy.

7.3.6 Induction with biological agents and maintenance with csDMARDs

Induction therapy with a biologic agent very early in the disease course followed by withdrawal of the biologic agent and maintenance with csDMARDs might also be a feasible approach to attain sustained good outcomes, but currently available data are not strong enough to allow for such a conclusion to be reached. This concept was introduced in a placebo-controlled study by Quinn et al (2005). The study showed that patients with early RA with poor prognostic factors treated with infliximab and MTX developed fewer MRI-detectable erosions at 12 months than patients treated with MTX alone. The functional and quality-of-life benefits obtained in patients treated with infliximab after 1 year was sustained at 2 years without further infliximab infusion.

The BeSt trial compared the use of four dynamic treatment strategies and examined the optimal treatment paradigms for early RA with symptoms <2 years. The four treatment strategies included a sequential monotherapy (strategy 1), step-up combination therapy (strategy 2), initial triple therapy with MTX, SSZ and high-dose prednisone (strategy 3) and initial combination therapy with infliximab + MTX (strategy 4), all followed by targeted treatment adjusted at 3-monthly intervals aiming at low disease activity DAS of ≤ 2.4 (Goekoop-Ruiterman et al, 2005). The two groups with initial intensive treatment (strategies 3 and 4) showed a more rapid clinical response, a better radiographic outcome and required fewer treatment adjustments, than groups 1 and 2, at 2 years. No significant differences in toxicity were noted between the groups.

After 5 years, 48% of patients were in clinical remission (DAS < 1.6). Of those, 46%, 51%, 65% and 81% of patients in groups 1–4 had achieved DAS <1.6 with the initial treatment. Of note, 14% were in drug-free remission, irrespective of initial treatment, and in years 2–5 annual progression was comparable across the groups (Klarenbeek et al, 2011). Further follow-up analysis from the BeSt trial showed that these effects persisted after 10 year follow-up (Markusse et al, 2016). 53% and 14% of patients were in remission and drug-free remission, respectively, without differences among the strategies; and radiographic damage was limited for all strategies. The authors conclude that initial (temporary) combination therapy results in faster clinical improvement, and that targeted tight control treatment (all study strategies) determines long-term outcomes.

The clinical and radiographic outcomes of induction therapy with or without biologics in early RA have been assessed in the OPERA randomized trial (Optimized Treatment Algorithm for Patients With Early Rheumatoid Arthritis) (Hørsley-Petersen et al, 2015). The patients were randomized to receive adalimumab or placebo added to treat-to-target strategy with MTX and intra-articular triamcinolone during the first year. SSZ and HCQ were added if disease activity persisted after 3 months. During year 2, synthetic DMARDs continued and adalimumab was stopped. Addition of adalimumab did not increase the proportion of patients who reached the DAS28-CRP < 3.2 treatment target. One year after adalimumab withdrawal, treatment profiles, clinical responses and radiographic progression did not differ between groups. Thus, treat-to-target strategy in early RA provided excellent 2-year clinical and radiographic disease control independent of adalimumab induction therapy.

7.3.7 Tapering of therapy in early RA

During last years, the concept of early intervention with methotrexate and biological DMARDs for early arthritis allowing drug discontinuation after achieving remission has emerged. There are however, no current recommendations on implementation of this concept in daily clinical practice.

The possibility of achieving drug-free remission after 1 year after early remission induction treat-to-target steered therapy was analysed within the IMPROVED study in patients with undifferentiated arthritis or early RA (Wevers-de Boer et al, 2015). The patients started treatment with MTX + high dose prednisone. Those

patients who achieved remission 44/53 joints DAS < 1.6 after 4 months (early remission), tapered prednisone to zero, and those still in remission after 8 months tapered MTX to zero by protocol. After 1 year of remission-steered treatment, 32% of the patients who had achieved early remission after 4 months were able to taper medication and achieved drug-free remission. No baseline characteristics were independently associated with achieving drug-free remission at 1 year, but remission was less often sustained in ACPA-positive patients.

Early suppression of disease activity in early arthritis patients may result in drug-free remission and prevent damage. In the following analysis from the IMPROVED study, 2-year clinical and radiological outcomes of two DAS-remission-steered treatment strategies were assessed (Heimans et al, 2016). Patients in early remission DAS < 1.6 after 4 months tapered and stopped medication. Patients who did not achieve early DAS-remission after 4 months were randomized to either MTX + SSZ + HCQ + low dose prednisone (arm 1) or to MTX + adalimumab (arm 2). At 4-monthly intervals, medication was tapered and stopped if DAS was < 1.6 but restarted, increased or switched if DAS was ≥ 1.6 . Patients who achieved early remission more often achieved drug-free remission after 2 years (29% of patients) than patients who needed additional treatment steps in the randomization arms (7% and 9% in the arms 1-2), and more patients with undifferentiated arthritis than with RA achieved drug-free remission (34% vs 19%). However, disease activity and radiologic damage progression in all patients were well suppressed. A matrix model predicting rapid radiological progression based on risk factors identified in recent onset active RA (1987 criteria) performed poorly in recent onset RA (2010 criteria) and undifferentiated arthritis. It suggests that known risk factors for damage progression (baseline CRP, erosion score, autoantibody status, and initial treatment choice) lose their impact with early remission steered treatment tapering and even stopping of DMARDs is thus feasible, and drug-free remission is achievable in a subset of patients.

With early and intensive treatment many patients with early RA attain remission. Tapering conventional synthetic DMARDs in patients with early RA in sustained remission has been addressed in the tRECH trial (the Rotterdam Early Arthritis Cohort) (Kuijper et al, 2016). Patients were randomised to initial treatment with triple DMARD therapy GC bridging or MTX monotherapy with GC bridging. Patients were evaluated every 3 months. In case DAS was > 2.4 treatment was switched to a TNF-blocker. In case DAS < 1.6 at 2 consecutive time points, tapering was initiated according to protocol. During 2 years of follow-up, 57% of patients achieved sustained remission regardless of initial treatment strategy. Flare rates (medication increase after tapering) were 41% and 37% within 12 months in patients tapering conventional DMARDs and TNF-blockers, respectively. In this trial, after flare, only 65% of patients tapering conventional DMARDs re-achieved remission within 6 months after treatment intensification.

The effects of reduction and withdrawal of treatment has been addressed in early DMARD-naïve active RA, who had a remission while receiving etanercept+MTX therapy, in the PRIZE study (Productivity and remission in a randomized controlled trial of etanercept vs, standard of care in early rheumatoid arthritis) (Emery et al,

2014). All patients received 50 mg of etanercept +MTX weekly for 52 weeks (open-label phase). More than 60% of the patients achieved remission DAS28 < 2.6 at weeks 39 and 52 and were randomized to receive 25 mg of etanercept+ MTX (combination-therapy group), MTX alone, or placebo for 39 weeks (double-blind phase). Patients who had qualifying responses at week 39 of the double-blind phase had all treatment withdrawn at that time and were followed to week 65 (treatment-withdrawal phase).

More patients in the combination-therapy group than in the MTX alone group or the placebo group had sustained DAS28 remission < 2.6 at weeks 76 and 91 (double-blind phase) in 63% vs 40% vs 23%, respectively. Although more than half of the patients maintained remission while tapering, withdrawal of etanercept was possible in less than half of the patients and complete withdrawal of DMARDs only in one-quarter of the patients (44% who had received combination therapy, 29% who had received MTX alone, and 23% who had received placebo were in remission). These results imply that the level of treatment reduction is associated with the relapse rates. Continuing combination therapy at a reduced dose resulted in better disease control than switching to MTX alone or placebo, however, many patients in the MTX alone group and in the placebo group were in remission by the end of the study and no significant between-group difference was observed in radiographic progression.

An analysis from the BeSt trial, comparing patients who received initial infliximab treatment (strategy 4) with patients receiving infliximab at a later stage (strategies 1–3), showed that 56% of patients in group 4 were able to successfully stop infliximab compared with only 15% in the other groups at 2 years. This suggests that by achieving early remission within the ‘therapeutic window of opportunity,’ patients may require less treatment later on in the disease course (Castro-Rueda et al, 2008). Moreover, the BeSt study also showed the sequence of DMARD tapering by demonstrating that re-initiation of the last DMARD regimen prior to tapering can restore remission in case of disease relapse.

Several other studies have examined the potential for stopping biological DMARD treatment after achieving low disease activity in early RA. In the OPTIMA study (Optimal protocol for treatment initiation with methotrexate and adalimumab) patients with early RA were randomized to receive MTX or adalimumab+MTX (Smolen et al, 2014). Patients in the adalimumab+MTX group who achieved the stable low disease activity target DAS28-CRP<3.2 at weeks 22 and 26 were randomized to adalimumab-continuation or adalimumab-withdrawal for an additional 52 weeks. Although a high proportion of patients who achieved low disease activity target at 6 months with adalimumab +MTX were able to maintain low disease activity after withdrawing of adalimumab, 91% vs 81%, and to maintain remission, 86% vs 66%. Thus, even if numerically somewhat different, outcomes were much the same whether adalimumab was continued or withdrawn in patients who initially responded to adalimumab + MTX. On the other hand, 18% of OPTIMA study patients had radiographic progression, which may indicate that some patients had not achieved full disease control entering withdrawal phase as a therapy target of DAS28-CRP-low disease activity was applied after rather

short period time (6 months) and reassessed over 4 weeks with the possibility that the therapy target was not sustained.

Also studies in early RA, when remission was achieved with non-anti-TNF biologics in combination with MTX, examined withdrawal of a biologic agent. The AVERT trial (Assessing Very Early Rheumatoid arthritis Treatment) (Emery et al, 2015) showed that abatacept + MTX demonstrated robust efficacy compared with MTX alone in early RA (<2 years of symptom duration) with a good safety profile. Patients who reached remission DAS28-CRP<2.6 (no minimal duration required) at month 12, entered a 12-month period of withdrawal of all RA therapies. While 61% and 42% of the patients reached remission in the abatacept+MTX and MTX alone groups, only 15% and 8% of the patients maintained remission at 12 and 18 months following treatment withdrawal. The high relapse rate in this study may be attributed to the fact that the study included patients with poor prognostic markers (a relatively long symptom duration, ACPA-positive and mainly RF-positive) and that all therapies, i.e. both abatacept and MTX, were rapidly stopped, further, a sustained remission was not ensured before therapy withdrawal, thus, tapering of the drugs may have been initiated too early.

These recent studies provide evidence for the rationale for the use of early intensive induction-treatment strategies with the potential to de-escalate induction-treatment when targeted disease control is achieved, and subsequently to taper maintenance-treatment when remission is sustained.

7.3.7 Treatment strategies: practical points

- Non-pharmacological and lifestyle measures form part of the treatment strategy. Of these, smoking cessation and weight reduction in obese patients are known factors that have effect on response to anti-rheumatic treatment and disease outcomes, apart from lowering cardiovascular risk, and should therefore be strongly encouraged.
- Early institution of effective treatment is the cornerstone of treatment for early arthritis. Treatment delay may be considered (if at all) only in those with very mild disease <3 months from onset. A single dose of IM steroid therapy may be advocated in this group. Arthritis that is persistent for >12 weeks is unlikely to resolve spontaneously (Quinn et al, 2003): many of these patients will progress to develop RA. DMARD treatment should be started in all patients with early arthritis in whom the disease is likely to develop into a persistent and/or erosive arthritis classifiable as RA.
- Consideration of the risk–benefit ratio and the cost-effectiveness of these strategies suggests that a reasonable course of action in early arthritis should be initial conventional synthetic DMARDs with NSAIDs and steroids as adjunctive treatment. In most cases MTX is the first preferred DMARD. Other csDMARDs—for example, sulfasalazine and leflunomide, are suitable alternatives.

- In DMARD-naïve patients with significant disease activity and risk factors for poor prognosis - for example, high titre RF or ACPA, early use of a more intensive strategy i.e. triple therapy or combination therapy of MTX and a biological agent might be considered.
- Induction of remission with a short-term treatment with a biological DMARD, maintenance with a conventional DMARD and subsequent drug de-escalation and discontinuation after achieving sustained remission is a potential therapeutic strategy for the future.

7.4 Monitoring of disease activity and achieving tight control

The objective of treatment is to achieve a state of low disease activity and ideally remission in order to prevent structural damage and long-term disability. Regular monitoring of disease activity is therefore necessary, increasing treatment if the disease is not controlled, and tapering treatment if the patient is in persistent remission. Imaging may assist with decisions about treatment decisions. The 'best' initial treatment may be less a matter of drug choice but more a matter of whether treatment target as defined by available scores as DAS28 <2.6 or DAS <1.6) are followed. It is not demonstrated if the treatment goal should be remission or low disease activity, but remission as the therapy target is suggested as the optimal goal. As patients may still have some continuing disease activity despite fulfilling the criteria for remission, ACR/EULAR have proposed and published two new definitions for application in RA clinical trials—summarised in box 4 (Felson et al, 2011).

Box 4 American College of Rheumatology/EULAR 2011 provisional definitions of remission for clinical trials

Boolean-based definition

At any point, a patient must satisfy all of the following:

Tender joint count ≤ 1

Swollen joint count ≤ 1

CRP ≤ 1 mg/dL

Patient global assessment ≤ 1 (on a 0–10 scale)

Index-based definition

At any point, a patient must have SDAI ≤ 3.3

CRP, C-reactive protein; SDAI, Simplified Disease Activity Index.

Reproduced from Felson et al, *Ann Rheum Dis* 2011;70:404–13.

In the TICORA (Grigor et al, 2004) ('tight control in RA') study, 110 patients with RA of <5 years' duration were randomly assigned to an intensive treatment in order to reach a low activity state (DAS44 < 2.4) close to remission, or to regular clinical care. Patient in the TICORA group were examined monthly and DMARD treatment was escalated according to a predefined strategy if the DAS44 was >2.4. Those in the group receiving routine care were seen every 3 months without formal assessment or feedback on disease activity scores and treatment adjusted according to the clinical judgement of the rheumatologist. The group receiving intensive treatment had significantly more remissions and developed less radiographic damage than the control group after 18 months of follow up. This strategy also resulted in higher treatment retention rate, a

lower rate of discontinuations due to side effects and lower costs per patient (based on lower admission costs) than routine care over the 18 months of observation. Of note, however, more intra-articular steroids were used in this treatment group.

The CAMERA (computer-assisted management of early RA) trial (Verstappen et al, 2007) also showed that monitoring and intensive treatment tailored to the individual patient are more beneficial than routine care. Of all, 299 patients with early RA were randomised to receive intensive or routine treatment with oral MTX. If necessary, treatment was changed to subcutaneous MTX and cyclosporine was added to achieve disease control if patients had an inadequate response to maximal tolerated MTX doses. Patients in the intensive treatment group were seen more frequently in clinic and dosages were adjusted based on predefined criteria and tailored to achieve remission using a computer-assisted programme. At 2 years, more patients in the intensive-management group achieved sustained remission for at least 3 months than in the routine care group (50% vs 37%). There was a better clinical effect nearly in all clinical variables for the intensive treatment group compared with the conventional treatment group (ESR, EMS, VAS for pain and general wellbeing, swollen and tender joint counts). In the intensive strategy group 50% of patients achieved at least one period of remission during the two year trial, versus 37% in the conventional strategy group. Patients in the intensive-management group also used fewer NSAIDs than those receiving routine care. However, a large proportion in the routine group also achieved excellent outcomes, illustrating that the intensive strategy is not necessary in every individual patient.

Results of the BeSt study (Behandel-Strategieën), showing good long-term clinical outcomes in all patients irrespective of the initial treatment strategy and sustained clinical and functional benefit as well as favourable survival prognosis, reinforce the importance of early intervention and treat-to-target steered treatment of early RA (Klarenbeek et al, 2011; Markusse et al, 2016). With evidence for the benefit of tight control (Fransen et al, 2005; Saunders et al, 2008; Schoels et al, 2010a), increasing numbers of clinical trials have incorporated treat-to-target approaches when examining optimal therapeutic strategies for patients with RA (Bakker et al, 2012; de Jong et al, 2014; Heimans et al, 2014; Nam et al, 2014b).

Regular monitoring of disease activity and adverse events should guide decisions on choice and treatment adjustment when necessary. This includes both conventional synthetic and biological DMARDs. Monitoring of disease activity should include tender and swollen joint count, patient's and physician's global assessment, ESR and CRP. Arthritis activity should be assessed at 1–3-month intervals, for as long as the target (remission) has not been achieved. Structural damage should be assessed by X-ray examinations about once a year for the first few years. Functional assessment, eg, the HAQ score, can be used to complement the disease activity and structural damage monitoring (Smolen et al, 2010*).

Recommendations for the management of early arthritis are summarised in box 5.

Box 5 EULAR recommendations on the management of early arthritis

1. Arthritis is characterised by the presence of joint swelling, associated with pain or stiffness. Patients presenting with arthritis of more than one joint should be referred to, and seen by, a rheumatologist, ideally within 6 weeks after onset of symptoms.
2. Clinical examination is the preferred method for detecting synovitis. In doubtful cases, ultrasound, power Doppler and MRI might be helpful to detect synovitis.
3. Exclusion of disease other than rheumatoid arthritis requires careful history taking and clinical examination, and ought to include at least the following laboratory tests: complete blood cell count, urine analysis, transaminases and antinuclear antibodies.
4. In every patient presenting with early arthritis to the rheumatologist, the following factors predicting persistent and erosive disease should be measured: number of swollen and tender joints, ESR or CRP, level of RF and ACPA, and radiographic erosions.
5. For patients at risk of developing persistent or erosive arthritis, treatment would be started with DMARDs as early as possible, even if they do not yet fulfil established classification criteria for inflammatory rheumatological diseases.
6. Patient information about the disease and its treatment and outcome is important. Education programmes aimed at coping with pain, disability and maintenance of work ability may be employed as adjunct interventions.
7. NSAIDs have to be considered in symptomatic patients after evaluation of gastrointestinal, renal and cardiovascular status.
8. Systemic glucocorticoids reduce pain and swelling and should be considered as adjunctive treatment (mainly temporary), as part of the DMARD strategy. Intra-articular glucocorticoid injections should be considered for the relief of local symptoms of inflammation.
9. Among the DMARDs, methotrexate is considered to be the anchor drug, and should be used first in patients at risk of developing persistent disease.
10. The main goal of DMARD treatment is to achieve remission. Regular monitoring of disease activity and adverse events should guide decisions on choice and changes in treatment strategies (DMARDs, including biological agents).
11. Non-pharmaceutical interventions, such as dynamic exercises, occupational therapy and hydrotherapy, can be applied as adjuncts to pharmaceutical interventions in patients with early arthritis.
12. Monitoring of disease activity should include tender and swollen joint count, patient's and physician's global assessments, ESR and CRP. Arthritis activity should be assessed at 1–3-month intervals, for as long as remission is not achieved. Structural damage should be assessed by radiographs of hands and feet every 6–12 months during the first few years. Functional assessment (eg, HAQ) can be used to complement the disease activity and structural damage monitoring.

ACPA, antibodies to citrullinated peptide; CRP, C-reactive protein; DMARD, disease-modifying antirheumatic drug; ESR, erythrocyte sedimentation rate; HAQ, Health Assessment Questionnaire; MRI, magnetic resonance imaging; NSAIDs, non-steroidal anti-inflammatory drugs; RF, rheumatoid factor.

Reproduced from Combe et al, Ann Rheum Dis 2007;66:34–45.*

8 Further research

Areas for further research include:

- The development and validation of diagnostic tests and strategies that enable general practitioners to recognise patients with clinically suspect arthralgia and early forms of arthritis as soon as possible and refer these patients to the rheumatologist
- The diagnostic and therapeutic strategies in the preclinical phase of RA
- The therapeutic strategies in early UA which could prevent development of RA
- The development of treatment regimens which can be subsequently tapered to induce drug-free remission
- The comparative effectiveness and cost-effectiveness of different therapeutic strategies.

SUMMARY POINTS

- Early diagnosis and treatment can prevent or delay the joint destruction, functional impairment and mortality associated with rheumatoid arthritis (RA).
- Early recognition of an inflammatory arthritis is therefore imperative.
- Patients with an inflammatory arthritis should be referred as early as possible to a rheumatologist for further management.
- In the earliest stages the arthritis may be undifferentiated. A combination of clinical, imaging and laboratory measures allow differentiation of inflammatory arthritis and RA.
- Patients with RA or undifferentiated arthritis must be evaluated for the risk of disease progression and severity.
- Early effective treatment should be instituted for those at risk of developing persistent and/or erosive arthritis.
- Treatment includes both pharmacological and non-pharmacological options.
- In the management of early arthritis combination of regular monitoring and optimal treatment interventions are paramount to achieve the target of therapy (remission or low disease activity) and improve outcomes of the disease.

Early arthritis: diagnosis and management

Sofia Ajeganova, Anca I. Catrina, Tom W.J. Huizinga

A previous version was co-authored by Jackie Nam, Anca Catrina, Paul Emery

IN-DEPTH DISCUSSION I

**Magnetic Resonance Imaging and Ultrasonography in
Early Arthritis**

The earlier inflammatory arthritis (IA) is detected, and treated, the better the long-term outcome in terms of damage and function. In the ESPOIR cohort, mean radiographic progression in patients with IA receiving very early therapy (within 3 months of diagnosis) was lower compared to those starting DMARDs later (0.8 units versus 1.7 units; $P = 0.033$, adjusting for disease specific and demographic factors influencing initiation of DMARD therapy).¹ Further benefit is obtained with regular monitoring of disease activity and rapid therapeutic adjustment to gain disease control. It is therefore important to have measures that are sensitive for the assessment of disease activity/function and monitoring of treatment in early arthritis.

Although conventional radiography (CR) is able to detect structural joint damage in patients with established disease, it is not sensitive for the detection of bone or soft tissue changes in the earliest stages.²⁻⁴ Newer imaging techniques, such as magnetic resonance imaging (MRI) and ultrasound have shown promise in this regard.⁵⁻⁸

Magnetic resonance imaging

MRI has several advantages compared to CR. It provides multi-planar images and is able to image a range of joint structures including synovium, tendons, tendon sheaths, entheses, ligaments, cartilage and bone with a high degree of resolution. Unlike CR, ionising radiation is not used.

Relative disadvantages include limited access to this imaging modality and high relative cost. The need for prolonged immobility can also present difficulties, especially for patients with much pain and stiffness. More recently, low-field dedicated extremity MRI units have been used⁹ with the advantages of lower costs, less claustrophobia and more comfortable positioning for patients. Its ability to detect synovitis however may be relatively low.¹⁰

Diagnosis

Synovitis, tenosynovitis and bone marrow oedema are features of inflammation seen on MRI. Histopathology and mini-arthroscopy have confirmed that these findings represent true inflammation.^{11,12} Bone oedema, which is a specific MRI finding, probably represents a cellular infiltrate within bone,¹³ occurs in various arthritides. It is common in early RA¹⁴ and is regarded as a precursor of erosions (see below). MRI detected tenosynovitis has also recently been reported as a feature commonly seen in early disease.¹⁵

Synovitis can be assessed using T2-weighted imaging, dynamic contrast-enhanced MRI or diffusion weighted imaging. Bone marrow oedema can be detected on fluid-sensitive sequences such as short-tau inversion recovery or T2-weighted fast-spin echo sequences. For detection of small bone erosions in the early erosive phase, T1-weighted MRI has demonstrated similar sensitivity to CT.¹⁶

More efficient MRI techniques come recently available for evaluating of bone marrow oedema. Thus, it has been shown that a shorter MRI protocol with T1 post-gadolinium chelate images (T1Gd) can replace T2-weighted images (T2).¹⁷

There is good evidence that MRI is a sensitive indicator of active disease.³ It is more sensitive than clinical examination for detecting synovitis.¹⁸ Erosions on MRI are also detected earlier on MRI than CR.¹⁹ These MRI findings may suggest that patients with undifferentiated arthritis have RA. In a cohort of patients with undifferentiated polyarthritis followed up over 2 years, MRI of the most symptomatic hand and whole-body scintigraphy correctly classified RA according to the 1987 classification criteria and non-RA in 39 of 41 patients.²⁰ The positive and negative predictive values for the development of RA of were 1.0 and 0.87 respectively. In another study assessing the diagnostic value of MRI, the presence of symmetric periarticular enhancement in the wrists, metacarpophalangeal or proximal interphalangeal joints increased the sensitivity for the clinical diagnosis of RA from 77% to 96%.²¹ In patients with UA, the presence of bone marrow oedema has been shown to increase the sensitivity of RA diagnosis (1987 classification) and use of DMARD therapy at one year compared to the 2010 ACR/ EULAR RA classification criteria, but the specificity was reduced.^{22 23} Findings were similar using MRI erosions.²³

Few studies have examined the use of MRI to differentiate RA from other arthritides. Although some small studies have shown that MRI signals of inflammation in RA are more frequent in the synovium than at the insertion of ligaments and tendons (entheses) with the converse being true for the spondyloarthropathies and early psoriatic arthritis, other studies have not found this to be sufficiently common to be of diagnostic use.²⁴ In a study of 179 patients with early arthritis, patients with RA according the 1987 classification criteria had higher scores for synovitis, tenosynovitis and bone marrow oedema than patients without RA. Patients who fulfilled the 2010 ACR/EULAR RA classification criteria but not ACR 1987 criteria for RA had less synovitis than patients who fulfilled both sets of RA criteria.²⁵ ACPA-positive patients had more bone marrow oedema than the ACPA-negative patients. For all MRI features, the predictive value for RA however was low, <50%. Whether this indicates a common pathology and thus low discriminatory ability between RA and other early arthritis by means of MRI remains to be determined.

Prognosis

There is evidence that the presence of bone oedema in patients with UA is predictive of the development of RA.²⁶ In patients with RA, MRI-detected synovitis, and more specifically bone oedema, precedes the development of erosions; furthermore, in joints lacking synovitis / bone oedema, erosions are unlikely to develop.²⁷ MRI-evident erosions and bone oedema have also been shown to predict subsequent radiographic erosions.²⁸⁻³⁰

Imaging findings alone are not diagnostic. The recent study has evaluated the use of MRI as an imaging biomarker in patients with clinically suspect arthralgia but without clinical synovitis. MRI scans were performed on the unilateral wrist, MCP joints 2-4 and MTP joints 1-5 of 93 patients.³¹ MRI inflammation was defined by a combined RAMRIS score of synovitis, bone marrow oedema and tenosynovitis ≥ 3 . In total 44% of patients were found to have MRI inflammation. Patients with MRI inflammation were more frequently anti-CCP antibody positive than those without MRI inflammation. Of 29 patients with MRI inflammation who were followed, 10 (34.5%) developed overt arthritis within 4 months. In another study of 28 ACPA-positive arthralgia patients with three years of follow-up, MRI synovitis was found in the majority of patients (93%).³²

Monitoring

MRI has been used as an outcome measure in clinical trials. Changes in synovitis scores have been calculated following therapy^{33 34} with a differential reduction between treatment groups favouring more intensive treatment regimes. Studies have also shown that, despite clinical remission, MRI synovitis may persist.¹⁸ These findings suggest a possible role for MRI in monitoring response to therapy.

Figure 1 - Magnetic resonance imaging picture of the wrist of a patient with early rheumatoid arthritis.

*T1 3D VIBE with fat suppression sequence - coronal plane showing synovitis of the wrist. This is seen as a well-defined area of ring enhancement just proximal to the carpus (blue arrow). There are also diffuse hyperintense regions within the carpus (**). A small erosion can be seen in the scaphoid (white arrow). LMBRU, University of Leeds, U.K.*

Figure 2 – Images of the wrist of a patient with rheumatoid arthritis.

A. Conventional radiograph. B. Pre- and C. Post-contrast T1 3D VIBE MRI images with fat suppression – coronal plane

The scaphoid erosion is not seen on the conventional radiograph (A) or the pre-contrast MRI image (B) but can be visualised on the post contrast MRI image (C). LMBRU, University of Leeds, U.K.

Figure 3 - Magnetic resonance imaging picture of the knee of a patient with rheumatoid arthritis.

T1 3D VIBE fat suppression image in the sagittal plane showing the medial aspect of the femur and tibia with areas of bone oedema. These are seen here as hyperintense areas within the bone (arrows). LMBRU, University of Leeds, U.K.

Ultrasound

Rheumatologists increasingly use ultrasound as a part of their clinical practice. Advantages of US include the ability to image both bone and soft tissue structures without using ionising radiation, allowing for repeat testing. Ultrasound is also relatively rapid to perform, less expensive than MRI and allows dynamic assessment of multiple joints in multiple planes. The main drawbacks are the limited visualisation of some joints and the operator-dependant nature of the modality.

Diagnosis

Similar to MRI, several studies have shown that ultrasound is sensitive for the detection of synovitis and joint effusion. Use of the Doppler technique (power Doppler, PD) further assists in the detection of inflammation. PD³⁵ is particularly suited for assessing tissues with low velocity blood flow, such as the synovium. Findings of bone oedema on MRI scans correlate with grey scale or PD grade of joint synovitis or presence of US bone erosions,³⁶ thus, US findings of inflammation have proven reliability for detecting joint inflammation.

Ultrasound is also more sensitive than CR for detecting joint erosions in patients with arthritis. In one study 6.5 fold more metacarpophalangeal erosions were documented using ultrasound compared to CR in early RA.³⁷ The greater sensitivity relates to the multi-planar capability of ultrasound (compared to the two-dimensional image with CR) and its ability to detect smaller erosions.

The ultrasound-guided joint aspiration may be diagnostic and may help in differentiating septic or crystal arthritides from other form of inflammatory arthritis. Studies have suggested that ultrasound signs of inflammation are more frequent in the joint than at tendon insertions (enthesitis) in RA, whilst ultrasound features of enthesitis are more common in the spondyloarthropathies.^{38 39} Specific patterns of crystal deposition have been described in gout and calcium pyrophosphate crystal deposition disease^{40 41} and peritenon extensor tendon inflammation in psoriatic arthritis.⁴²

Prognosis

Ultrasound has been suggested to be of value in determining persistence of very early IA.⁴³ In a small study in RF and ACPA-negative patients with ≤ 12 weeks of inflammatory symptoms, the addition of clinical and radiographic features raised the probability of certainty of IA diagnosis/persistence of IA after 12 months from 6% to 30%, and additionally with certain ultrasound features the probability of IA rose to 94%.

Ultrasound measures of synovial thickening and vascularity at baseline have some correlation with future X-ray defined joint damage.⁴⁴ A study examining the progression of erosive disease in 21 patients with early RA has showed that, compared with CR (Sharp van der Heijde method), ultrasound detected 17-fold more joints with erosions at baseline (defined as cortical defects greater than 2 mm in diameter with an irregular floor) and 7.6-fold more joints with erosions after 6 months.⁴⁵ The detection of radiographic erosions is an essential diagnostic criterion in RA, and a valuable measure of prognosis and disease severity. Although US is more sensitive in establishing the presence of erosive joint disease, the prognostic value of US-detected erosions is unknown. Further, the specificity of US-detected erosions for diagnosis of RA, other arthritis and osteoarthritis is not clear.⁴⁶

A phase of preclinical RA, with rising titres of autoantibodies and suspect (inflammatory) arthralgia is now recognized. The role of ultrasound has also been evaluated in patients at risk for development of clinical arthritis. In anti-CCP positive individuals with new non-specific musculoskeletal symptoms but without clinical synovitis, tenderness of hand or foot joints, early morning stiffness ≥ 30 min, high levels of RF and anti-CCP autoantibodies, and positive PD strongly associated with progression to inflammatory arthritis, mostly within the first 12 months.⁴⁷ In another study examining the use of ultrasound in patients with RF-positive and/or anti-CCP positive arthralgia, ultrasound was found to be predictive of the development of IA at a joint level, but not at a patient level.⁴⁸

Monitoring outcomes

Ultrasound findings, in particular the presence of PD, are also found to be sensitive and reliable for longitudinal assessment of the inflammatory disease activity in early RA.⁴⁹ Some studies have shown that ultrasound synovitis may still be present in patients on DMARDs in clinical remission suggestive of subclinical inflammation that is not detected by clinical evaluation.^{50 51} However the randomised TaSER study in 111 patients with newly diagnosed RA or undifferentiated arthritis, followed for 18 months, has shown that ultrasound assessments, additionally used as a part of a treat-to-target treatment strategy, did not improve clinical or imaging (MRI and radiographic erosions) outcome in RA patients but led to significantly more treatment changes and more intensive treatment than DAS28-driven treatment strategy.⁵²

A systematic literature review and meta-analysis found US-detected synovitis to be prevalent in patients with RA in clinical remission.⁵³ Monitoring disease activity and remission, the time relationship between clinical and US findings is essential. However, so far the time-frame for these changes is not known. Interestingly, it has been reported that in clinical remission, DAS28<2.6, joints showing higher grey scale US-signals has significantly shorter time since last clinical swelling and positive US assessments as compared with those with lowered grey scale signals. A similar trend was shown with PD signals.⁵⁴

The presence of US findings is suggested to predict the relapse and progression of structural damage after discontinuation of treatment.⁵³ One of the recent studies has investigated the value of US for predicting a failure to taper a biologic agent in 42 patients with RA. Relapse rates were significantly higher in patients whose total ultrasound scores (grey-scale and PD scores in 40 joints) at discontinuation were high than in those whose total ultrasound scores were low, whereas the difference between DAS28 scores was not statistically significant. Positive and negative predictive values for the total grey-scale scores were 80% and 73%, and for the total power Doppler scores 89% and 74%, respectively.⁵⁵ In this study, residual synovial inflammation determined by US assessment predicted relapse within 6 months after discontinuing biological DMARD.

There are currently no standards on the optimal number and combination of joints to be assessed by US in daily practice. The time course relationship between anatomical, ultrasound and clinical changes is not defined which limits the value of US imaging for monitoring of disease activity/remission and response to treatments in arthritis.

In summary:

Accurate methods for the diagnosis, prognostic assessment and monitoring of treatment of early arthritis are essential. MRI and ultrasound are more sensitive imaging modalities than CR for visualising early inflammatory and destructive change in RA and predicting future radiographic damage. Relative high costs, long examination times and low availability, however, limit the widespread use of MRI. In comparison, ultrasound is relatively inexpensive, non-invasive and allows assessment of many joints. The main disadvantage of this modality is its dependency on the skills of the operator and potential problems with reproducibility. Table 1 shows a summary of some of the differences between the 3 imaging modalities.

The role of ultrasound and MRI in clinical practice and within clinical trial setting continues to grow (table 2). EULAR recommendations for the use of imaging modalities including CR, ultrasound and MRI of the joints in RA management have recently been published but the level of evidence is low (Table 3).⁵⁶ Therefore further research is ongoing to address various aspects of the role of these imaging modalities in assessment of early arthritis, including their role in the pre-clinical phase of the disease, differentiating early RA from other diseases and determining prognosis. So far imaging added to clinical assessment for monitoring of disease activity has not proven to be of benefit for the patient. Several studies are underway to determine whether targeting subclinical inflammation detected by MRI or ultrasound could improve outcomes in patients with early arthritis.⁵⁷

Table 1. Comparison of conventional radiography, MRI and ultrasound

	Conventional Radiography	MRI	Ultrasound
Tolerance	Excellent	Fair	Excellent
Ionizing radiation	Yes	No	No
Time to perform	Short	Long	Intermediate
Cost	Inexpensive	Expensive	Inexpensive
Ease of accessibility	Easy	Intermediate/difficult*	Easy- Difficult*
Operator dependant	No	No	Yes
Number of joints per session	Many	Few	Many
Planes	One	Multi	Multi
Real-time scanning	No	No	Yes
Bone visualisation	Good	Excellent	Good(cortex only)
Soft tissue visualisation	Non-specific	Excellent	Excellent
Allows intervention	Yes (fluoroscopy)	No	Yes

Table 2. Use of MRI and musculoskeletal ultrasound in the management of early arthritis in clinical practice and research

Diagnosis and classification of RA
Diagnosis of other inflammatory arthritides e.g. ultrasound guided joint aspiration for septic arthritis and gout
Predicting progression to RA in individuals at risk and in patients with UA
Determining treatment escalation as part of treat-to target strategies
Monitoring of disease activity on treatment
Predicting response to treatment
Determining treatment de-escalation in patients with RA in clinical remission

Table 3. EULAR recommendations for the use of imaging of the joints in the clinical management of rheumatoid arthritis⁵³

Recommendation*	SOR, mean VAS 0-10 (95% CI)	Level of evidence
1. When there is diagnostic doubt, CR, ultrasound or MRI can be used to improve the certainty of a diagnosis of RA above clinical criteria alone. †	9.1 (8.6 to 9.6)	III
2. The presence of inflammation seen with ultrasound or MRI can be used to predict the progression to clinical RA from undifferentiated inflammatory arthritis.	7.9 (6.7 to 9.0)	III
3. Ultrasound and MRI are superior to clinical examination in the detection of joint inflammation; these techniques should be considered for more accurate assessment of inflammation.	8.7 (7.8 to 9.7)	III
4. CR of the hands and feet should be used as the initial imaging technique to detect damage. However, ultrasound and/or MRI should be considered if point (especially in early RA) conventional radiographs do not show damage and may be used to detect damage at an earlier time.	9.0 (8.4 to 9.6)	IV
5. MRI bone oedema is a strong independent predictor of subsequent radiographic progression in early RA and should be considered for use as a prognostic damage detected by conventional radiographs, MRI or ultrasound can also be considered for the prediction of further joint indicator. Joint inflammation (synovitis) detected by MRI or ultrasound as well as joint damage.	8.4 (7.7 to 9.2)	III
6. Inflammation seen on imaging may be more predictive of a therapeutic response than clinical features of disease activity; imaging may be used to predict response to treatment.	7.8 (6.7 to 8.8)	III-IV
7. Given the improved detection of inflammation by MRI and ultrasound than by clinical examination, they may be useful in monitoring disease activity.	8.3 (7.4 to 9.1)	III

8. The periodic evaluation of joint damage, usually by radiographs of the hands and feet, should be considered. MRI (and possibly ultrasound) is more responsive to change in joint damage and can be used to monitor disease progression.	7.8 (6.8 to 8.9)	III
9. Monitoring of functional instability of the cervical spine by lateral radiograph obtained in flexion and neutral should be performed in patients with clinical suspicion of cervical involvement. When the radiograph is positive or specific neurological symptoms and signs are present, MRI should be performed.	9.4 (8.9 to 9.8)	III
10. MRI and ultrasound can detect inflammation that predicts subsequent joint damage, even when clinical remission is present and can be used to assess persistent inflammation.	8.8 (8.0 to 9.6)	III

Recommendations are based on data from imaging studies that have mainly focused on the hands (particularly wrists, metacarpophalangeal and proximal interphalangeal joints). There are few data with specific guidance on which joints to image.

† In patients with at least one joint with definite clinical synovitis, which is not better explained by another disease.

Categories of evidence: Ia, evidence for meta-analysis of randomised controlled trials; Ib, evidence from at least one randomised controlled trial; IIa, evidence from at least one controlled study without randomisation; IIb, evidence from at least one other type of quasi-experimental study; III, evidence from non-experimental descriptive studies, such as comparative studies, correlation studies and case-control studies; IV, evidence from expert committee reports or opinions or clinical experience of respected authorities, or both.

CR, conventional radiography; RA, rheumatoid arthritis; SOR, strength of recommendation; VAS, visual analogue scale (0-10; 0=not recommended at all, 10=fully recommended).

IN-DEPTH DISCUSSION II

Pathogenic mechanisms at disease onset in early arthritis

The outcome of early, undifferentiated inflammatory arthritis may be one of spontaneous remission or persistent disease. If the latter, it may remain undifferentiated, or progress to rheumatoid arthritis (RA) or another distinct rheumatic disease. While mechanisms of self-limiting disease are poorly understood, new insights into the development of persistent disease - in particular anti citrullinated proteins antibody (ACPA)-positive inflammatory arthritis - have emerged in recent years.

The phases of development of seropositive RA-disease are described as seroconversion, antibody maturation, disease onset and disease outcomes.

The first insights in the pre-clinical phases of RA came with the observation that ACPA are present several years before disease onset in the peripheral blood of patients who eventually develop RA (1,2). Findings in this pre-clinical phase will depend on several factors including the individual at risk, the stage at which the person presents and if imaging techniques, e.g. ultrasound (US) and magnetic resonance imaging (MRI) are used, which joints are evaluated. Patients therefore may be ACPA-positive but have no clinical or imaging joint involvement or they may be at the stage of imminent RA in which there may be imaging findings in the absence of clinical synovitis (3).

Arthralgia with or without synovitis in individuals being ACPA-positive provides a high risk for future development of RA (4,5). Changes in bone metabolism have also been described in ACPA-positive individuals who do not yet have arthritis (6).

The occurrence of these autoantibodies without clinical and or imaging signs of joint inflammation (7) in individuals at risk for RA poses an interesting question in terms of the primary site of RA pathogenesis and has given rise to the idea that the initial immune challenge might happen at sites other than the joint.

Epidemiologic findings have previously revealed a very strong association between smoking and development of ACPA-positive RA, with those being smokers and having two copies of the shared epitope (SE) having a relative risk of 21 (CI 11.0-40.2) of developing rheumatoid arthritis compared to a relative risk of 3.3 (CI 1.5-8.9) in those who never smoked and had no SE genes (8). In contrast, no such association was observed in ACPA-negative disease.

The composition of the immune response to citrullinated antigens has been studied intensively. It appeared that many different citrullinated protein antigens present in the synovial compartment can be recognized by ACPA. This is most likely a consequence of the cross-reactivity the ACPA response displays to citrullinated proteins. It is now also clear that the isotype usage and the citrullinated epitope repertoire recognized by ACPA expands before the manifestation of full-blown Rheumatoid Arthritis and that this goes hand-in-hand with a rise in ACPA-level. Next to ACPA, several other auto-antibody systems directed against other post-translationally modified proteins, such as proteins containing an homo-citrulline residu resulting from protein carbamylation, have been identified. By and large, the evolution of these auto-antibody systems in time

mimics the evolution of the ACPA-response, indicating that the break of tolerance underlying different auto-immune responses present in RA occurs before disease onset, with a further maturation of these responses shortly before- or concurrent with the manifestation of clinical symptoms (reviewed in Dekkers et al 2016) (9).

Very interestingly the association of HLA class II antigens was less frequently present in healthy ACPA positive twins than in twins with ACPA-positive RA (10), neither in healthy ACPA-positive Japanese people there is no association with HLA class II antigens. A similar observation has been made for the RA-protective HLA alleles (HLA-DRB1*13), which do not protect from ACPA-positivity in individuals without RA but protect against the maturation of the ACPA response (11). These findings suggest that genetic predisposition has a role in transition from ACPA-seroconversion to early arthritis. How HLA class II locus links to T-cell responses leading to evolution of RA has been discovered in the recent study. Citrullinated vinculin, present in the joints of ACPA (+) RA patients, was identified as an autoantigen targeted by ACPA and CD4 (+) T cells. (12) These T cells recognize an epitope with the core sequence DERAA, which is also found in many microbes and in protective HLA-DRB1*13 molecules, presented by predisposing HLA-DQ molecules. Moreover, these T cells cross react with vinculin-derived and microbial-derived DERAA epitopes, suggesting that a microbial infection is the initiator of ACPA maturation and hence development of RA. Intriguingly, DERAA-directed T cells were not detected in HLA-DRB1*13(+) donors, indicating that the DERAA epitope from HLA-DRB1*13 mediates (thymic) tolerance in these donors and explaining the protective effects associated with HLA-DRB1*13. These data indicate the involvement of pathogen-induced DERAA-directed T cells as the molecular basis in the HLA-RA association. Currently research is ongoing to identify such a microbial contributor to the pathogenetic event that takes place during the pre-clinical phase of ACPA-positive RA (12).

It has been suggested that certain immunologic events, in the context of a signal that breaks self-tolerance, with enhanced expression of citrullinated antigens in extra-articular tissues may trigger auto-immunity and lead to formation of pathogenic ACPA antibodies, and thus, initiate and/or mediate immunological response in RA. Thus, smoking leads to more citrullinated antigens and ACPA formation in the lungs (13).

Apart from the lungs, the oral (14) and gut microbial dysbiosis could mediate the break of self-tolerance leading to excessive protein citrullination. Several clinical and epidemiologic studies have suggested that periodontitis is more prevalent in patients with RA and that periodontitis could be a causal factor in the initiation and maintenance of the autoimmune inflammatory response in RA. However, the strength and temporality of this association are uncertain. The epidemiological evidence for the association between chronic periodontitis and ACPA-positive RA is weak. One of the most known aetiological agents of periodontitis is *Porphyromonas gingivalis*, a bacterium possessing its own peptidyl arginine deiminase. It is unclear if this bacterial can induce or mediate citrullination of proteins in the human gingiva. Studies in individuals at risk for developing RA have demonstrated different results regarding titers of anti *P. gingivalis* antibodies compared to healthy controls. Patients with RA might show an increased risk of developing periodontitis through various

mechanisms. Exposure to common genetic, environmental and behavioural factors might contribute to a non-causal association between both conditions. This remains however to be established whether citrullination process in the extra-articular tissues precedes evolution to RA, whether citrullination in the extra-articular tissues and joints of RA patients shares immune targets and whether these immune targets are auto-antigenic.

While studies of pre-clinical and early phases of ACPA-positive RA have led to the insights into the development of the disease, studies in ACPA-negative RA have not been as successful. This fact might have several explanations: 1) more than one disease phenotype within the ACPA-negative subset; 2) lack of serological markers to identify healthy individuals at risk and distinguish the patients with seronegative RA; 3) insufficient knowledge of genetic, environmental and immune factors responsible for seronegative RA-disease. Studies to address this subset of disease are needed. Further research should also focus not only on understanding of mechanisms of persistent disease but also on mechanisms of self-limiting arthritis.

LEARNING OUTCOMES

- ➔ Describe how environmental, genetic and immunological mechanisms interact in the pathogenesis of the disease
- ➔ Explain the relationship between undifferentiated arthritis and rheumatoid arthritis (RA)
- ➔ Describe the characteristic pattern of joint involvement in early and established disease
- ➔ State and describe the typical extra-articular manifestations
- ➔ Describe the most commonly used tests for assessment of disease activity and health-related quality of life
- ➔ Use this knowledge in diagnosis and assessment of RA

1 Pathogenesis of rheumatoid arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory disorder that typically affects small and medium-sized joints symmetrically. The primary lesion is synovitis whereby immune cells invade the normally relatively acellular synovium, leading to the formation of inflammatory 'pannus'. This hyperplastic, invasive tissue causes cartilage breakdown, bony erosion and, ultimately, loss of function of the affected joint(s). Systemic involvement—for example, of the respiratory, cardiovascular and haematopoietic systems, may also occur. Consequently, the risk of atherosclerosis and lymphoma development is increased. Because of this, uncontrolled RA is associated with a reduction in life expectancy, which in some studies amounts to 6–7 years.

For the clinician, the striking heterogeneity of clinical presentation, natural history and drug responsiveness in RA means that it remains as challenging to manage as it is fascinating to study. This heterogeneity extends to a molecular level and, intriguingly, recent analyses of genetic risk factors, autoantibodies and drug responsiveness indicate that it may one day be possible to stratify the disease into prognostically and therapeutically meaningful subsets close to the time of symptom onset, permitting individually targeted treatments, with obvious benefits in clinical outcomes and cost. These ideals remain far off, however, but lie behind the need for an ever improved understanding of the pathophysiology of RA.

In this section, current and evolving concepts in RA pathogenesis are considered (figure 1). We focus on RA as a putative autoimmune disease, the role of autoantibodies in disease stratification and the associated genetic epidemiology. We summarise the molecular pathways involved, emphasising established and emerging therapeutic targets.

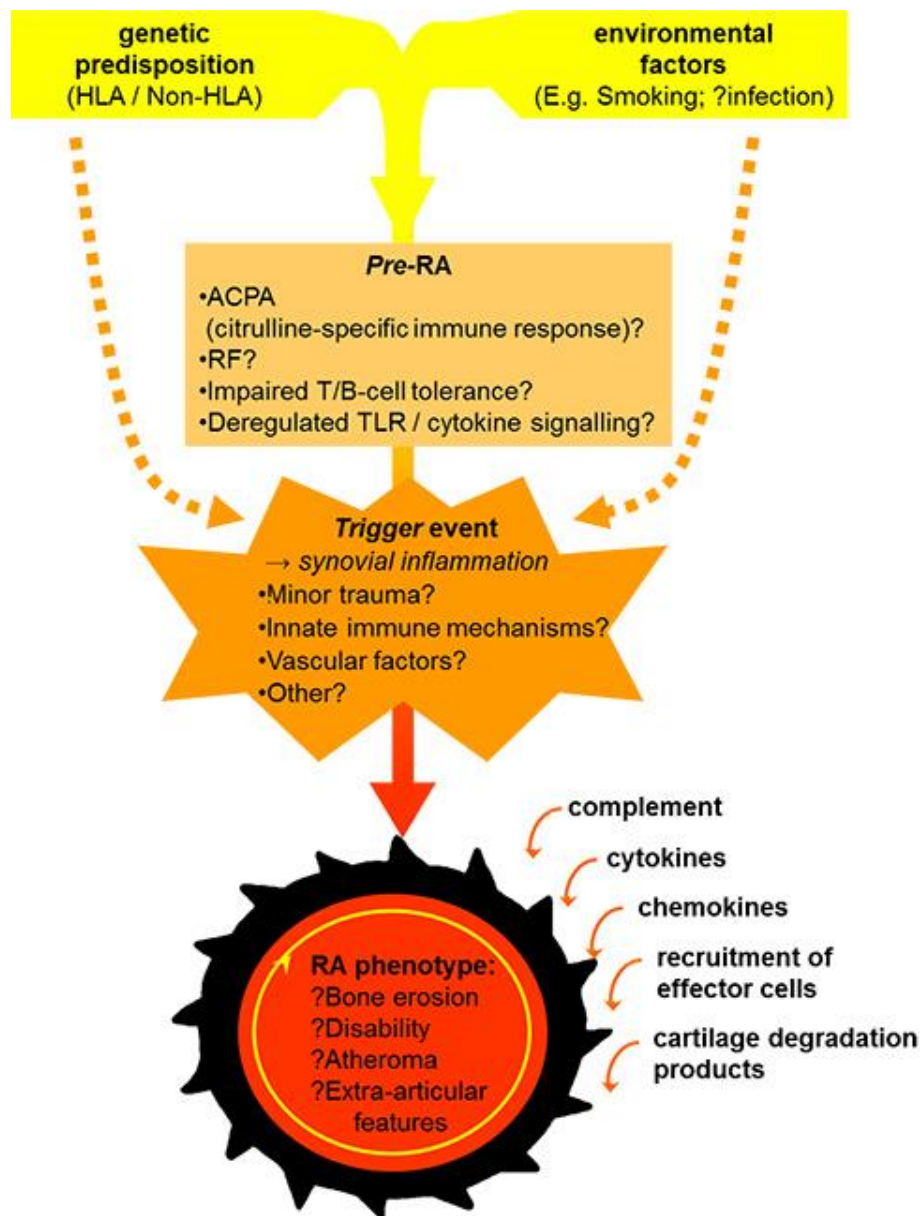

1.1 Epidemiology of RA

RA affects approximately 0.5–1% of European and North American adults, with considerable regional variation. Prevalence estimates for Southern European countries (median of 3.3 cases per 1000) are lower than for Northern Europe (5.0 per 1000) and highest rates are found in North America (10.7 per 1000) (Alamanos et al, 2006). Asian studies report between 2.8 and 3.5 cases per 1000, but the disease is said to be less common in rural Africa. In some Native American tribes up to 5% of individuals are affected.

Annual incidence rates are estimated to be 16.5 cases (per 105) in Southern Europe, compared with 29 in Northern Europe and 38 in North America (Alamanos et al, 2006). Women are about three times more frequently affected than men. The peak age of incidence for women is between 50 and 60 years and somewhat surprisingly for men is >70 years (Carbonell et al, 2008). RA presenting after the age of 60–65 is often referred to as late-onset RA or 'LORA'. It has long been documented that RA clusters in families: the likelihood that a first-degree relative of a patient will share the diagnosis is 2–10 times the population

prevalence of the disease, and recurrence risks are highest for relatives of the most severely affected index cases.

Figure 1 Schematic representation of factors relevant for the development of RA. Genetic and environmental determinants interact to create an adverse immune state in the predisposed individual, which may include the generation of circulating ACPA. When, how and why a 'trigger event' subsequently causes pathology to become focused in the synovium, is unknown, but it probably involves the innate immune system and further interaction of genetic and environmental factors. A self-perpetuating inflammatory cascade follows, producing the clinically recognisable, albeit heterogeneous, RA phenotype. ACPA, anti-cyclic citrullinated peptide antibodies; HLA, human leucocyte antigen; RA, rheumatoid arthritis; RF, rheumatoid factor; TLR, Toll-like receptor.

1.2 Autoantibodies: RA as an autoimmune disease

Witebsky postulated in 1957 that a disease must fulfil three criteria to be considered autoimmune in nature. A contemporary understanding of these postulates requires (1) the presence of autoantibodies or a cell-mediated immune response against an autoantigen, (2) that the respective autoantigen is known and (3) that a similar disease can be initiated in animals based on an analogous immune response (Witebsky et al, 1957; Rose and Bona, 1993). The status of RA as an autoimmune entity, while generally accepted, remains somewhat controversial based on these requirements. For example, although an array of antibodies targeting 'self' antigens (including collagen type II, calreticulin, cathepsin, BiP, CH65 and human collagen glycoprotein 39) has been described, the identity of a dominant arthritogenic autoantigen has remained elusive. Moreover, although inflammatory arthritis of autoimmune aetiology and with phenotypic similarities to human RA, may be artificially induced in animals (as in the example of collagen-induced arthritis), the direct relevance of such models to human disease has been difficult to demonstrate.

1.2.1 Rheumatoid factor

The initial notion that mechanisms of autoimmunity might underlie RA pathogenesis came from the discovery of autoantibodies targeting the Fc part of human IgG (so called 'rheumatoid factors' (RFs)) in the blood of affected patients (Franklin et al, 1957; Waaler, 2007). RFs, present mostly as IgM-RF, but detectable in subgroups of patients also as IgG-RF and IgA-RF, are thought to form immune complexes activating complement in the joint, which in turn leads to increased vascular permeability and the release of chemotactic factors recruiting immune-competent effector cells to the joint (Zvaifler, 1973). The mere presence of RFs, however, is insufficient to initiate arthritis development, as RFs are also found in infectious diseases, autoimmune diseases other than RA and in up to 15% of healthy, mostly elderly, individuals. Although the specificity of RF for diagnosis of RA is limited, raising the cutpoint for consideration of positivity to 50 IU increases its diagnostic test properties to those observable for ACPA (Nell et al, 2005; Nielen et al, 2005), i.e. providing a positive predictive value for RA in patients with early arthritis of >90%. For that reason the presence of RF was one of seven diagnostic criteria for RA put forward by the American College of Rheumatology in 1987 (Arnett et al, 1988*) and has also been included in the ACR/EULAR 2010 classification criteria for RA, particularly with additional credit for high positive RF levels (Aletaha et al, 2010).

1.2.2 Anti-citrullinated peptide antibody

Citrullination is a process by which arginine residues in a given protein are post-translationally modified ('deiminated') in the presence of high calcium concentrations by an enzyme called PAD (peptidylarginine deiminase) (figure 2). Citrullination is a physiological process, which is believed to be important for degradation of intracellular proteins during apoptosis. In 1998, two antibodies present in serum samples from patients with RA that had already been described years earlier (so called antiperinuclear factors, discovered in

1964 (Nienhuis and Mandema, 1964) and anti-keratin antibodies, first described in 1979 (Young et al, 1979) were found to share a common specificity for citrullinated filaggrin (Schellekens et al, 1998*; Girbal-Neuhauser et al, 1999). This observation placed citrullinated proteins at the centre of autoantibody research in RA. Citrulline-specific reactivities against a number of additional citrullinated proteins (eg, fibrinogen, vimentin and α -enolase) have since been identified. Using new assays that employ synthetic cyclic citrullinated peptides (CCP) as antigens, anti-citrullinated protein antibodies (ACPA) are found in 60–70% of patients with RA, with a high specificity for RA (van Gaalen et al, 2005). The extent to which ACPA are directly involved in RA pathogenesis is subject of continuing research.

Figure 2 Schematic representation of the enzymatic role of peptidylarginine deiminase (PAD) in the generation of citrulline from arginine residues.

Circumstantial evidence for their role in disease induction comes from observations that ACPA can be detected in sera several years before clinical onset of arthritis (Nielen et al, 2004), that their presence predicts progression from undifferentiated arthritis (UA) to RA (van Gaalen et al, 2004) and that they are associated with a more severe course of disease (Meyer et al, 2006). Longitudinal studies and studies in healthy relatives of ACPA-positive patients with RA have shown that the number of citrullinated epitopes recognised by ACPA increases during the development of RA (epitope spreading), that their avidity continues to increase until the onset of clinical disease (Suwannalai et al, 2012), and that the isotype repertoire of these autoantibodies concurrently expands (Ioan-Facsinay et al, 2008; Brink et al, 2013*). After diagnosis, however, the ACPA epitope recognition profile and the isotype repertoire remain remarkably constant. Interestingly, IgM-ACPA are detectable in samples from patients with early as well as longstanding RA, indicating that new antibody-secreting cells are continuously generated, which reflects an ongoing immune response (Verpoort et al, 2006).

Among the different ACPA specificities identified so far, citrullinated vimentin is identical to the previously described and highly RA-specific Sa antigen (Vossenaar et al, 2004). Specific mutations of vimentin have been detected in RA synovial fluid, and serum titres of antibodies targeting these mutated isoforms (called mutated citrullinated vimentin) correlate with disease activity (Bang et al, 2007). It is not clear if measurement of these autoantibodies will add value to CCP for diagnostic purposes in early arthritis (Mathsson et al, 2008; Raza et al, 2010).

Experimentally, elegant animal studies suggest that ACPA positivity may soon be said to define a subgroup of RA with a full set of 'autoimmune' credentials as originally defined by Witebsky (Kuhn et al, 2006; Hill et al, 2008; Uysal et al, 2009). Complementing these murine studies, additional data supporting ACPA pathogenicity come from in vitro experiments studying human ACPA. Human ACPA can activate complement by both the classic and the alternative pathway, and ACPA-containing immune complexes can induce tumour necrosis factor α (TNF α) production by human macrophages (Clavel et al, 2008; Trouw et al, 2009). The important influence of genetic and environmental factors on ACPA status in humans is outlined in detail below.

1.3 Genetic risk factors

Twin studies permit an estimation of heritability (the extent to which the likelihood of developing a condition in a population can be explained by genetic variation), and on the basis of studies in British and Finnish populations the heritability of RA has been calculated to be 60% (John et al, 1998). Many genetic variations that show an association with RA have been identified within the past few years owing to technical advances in genotyping and they are summarised here. Intriguingly, the majority of these associations apply primarily to ACPA-positive RA, being either absent or less robust for its ACPA-negative counterpart (table 1). Thus, there appears to be a genetic difference between ACPA+ and ACPA- patients, although the similarity of the clinical phenotype of disease and thus the clinical implications of this difference in genetic associations is currently still unclear. An important goal in the research of genetic contributions to RA is to investigate the specific functional role of each of the genetic variants. Functional roles have been described for only a handful of variants – some of them comprise increased susceptibility to developing RA and/or progressive disease, while others may even exert a protective effect. Furthermore, a growing interest has developed for genetic variants associated with efficacy and safety of medications used in RA. In addition to the efforts to describe the qualitative effect of each genetic factor, a quantitative approach is also required to assess the extent to which a genetic variant really contributes to a disease-related process. It should be taken into account that variants exerting a specific effect in one population may have almost no effect in another population (Chung et al, 2016).

For completeness, associations have been suggested for the following genes/loci listed in table 1. Most genetic associations have been shown for ACPA positive patients, while HLA-DRB1, PTPN22, STAT4, TNFAIP3, and IRF5 have been found also in ACPA negative patients.

Table 1 Genetic associations with ACPA-positive and ACPA-negative RA

<i>Gene/locus</i>	<i>Full name</i>	<i>Role of gene product</i>
HLA-DRB1	human leukocyte class II antigen	antigen presentation
HLA-DPB1	human leukocyte class II antigen	antigen presentation
HLA-B	human leukocyte class I antigen	antigen presentation
PTPN22	protein tyrosine phosphatase N22	regulator of T-cell receptor signaling
STAT4	signal transducer and activator of transcription 4	transcription factor
TNFAIP3	TNF α -induced protein 3	mediator of inflammation
BLK	BLK protooncogene	B-cell signaling and development
GIN1/C5orf30	gypsy retrotransposon integrase 1, chromosome 5 open reading frame 30	unclear
ANKRD55/IL6ST	ankyrin repeat domain 55/interleukin 6 signal transducer	signal transducer
PADI4	peptidyl arginine deiminase 4	converting arginine to citrulline
TRAF-1	TNF receptor associated factor 1	signal transducer
CTLA4	cytotoxic T-lymphocyte associated protein 4	inhibition of T-cells
KIF5A/PIP4K2C	kinesin family member 5A/phosphatidylinositol-5-phosphate 4-kinase type 2 gamma	intracellular microtubule motor
CCL21	C-C motif chemokine ligand 21	mediator of T-cell chemotaxis
CD28	cluster of differentiation 28	T-cell proliferation, Th2 development
PRDM1	PR domain 1	repressor of IFN- β expression

CD2/CD58	clusters of differentiation 2/58	T-cell surface antigen/adhesion of T-cells
IL2RA	interleukin 2 receptor subunit alpha	subunit of the IL-2 receptor
TYK2	tyrosine kinase 2	protein of the JAK kinase family
IRAK1	interleukin 1 receptor associated kinase 1	upregulator of NF-kappa-B
TLE3	transducin-like enhancer of split 3	role in the Notch pathway of cell development
RASGRP1	RAS guanyl releasing protein 1	regulator of T- and B-cell development
IL-6R	receptor of IL-6	cytokine receptor
IRF8	interferon regulatory factor 8	transcription factor
ARID5B	AT-rich interaction domain 5B	regulator of B-cell differentiation
IKZF3	IKAROS family zinc finger 3	regulator of B-cell differentiation
RUNX1	runt related transcription factor 1	development of haematopoiesis
POU3F1	POU class 3 homeobox 1	unclear
RCAN1	regulator of calcineurin 1	role in CNS development and dementia
CD5	cluster of differentiation 5	T-cell surface marker
GATA3	GATA binding protein 3	regulator of T-cell development
RBPJ	recombination signal binding protein for immunoglobulin kappa J region	regulator of the Notch pathway
CCR6	C-C motif chemokine receptor 6	B-cell maturation, T-cell migration
CD40	cluster of differentiation 40	receptor on antigen presenting cells
MMEL1	membrane metallo-endopeptidase-like 1	regulator of pain perception
AFF3	AF4/FMR2 family member 3	transcription factor in lymphoid tissue
REL	REL proto-oncogene, NF-kB subunit	regulator of immune response

DNASE1L3	deoxyribonuclease I like 3	mediator of apoptosis
IRF5	interferon regulatory factor 5	transcription factor
IL-2RB	interleukin 2 receptor subunit beta	subunit of the IL-2 receptor
DDX6	DEAD-box helicase 6	suppressor of translation
SPRED2	sprouty related EVH1 domain containing 2	regulator of the MAP kinase cascade
TAGAP	T-cell activation RhoGTPase activating protein	regulator of signaling pathways
PTPRC	protein tyrosine phosphatase, receptor type C	regulator of T- and B-cell antigen receptor signaling
PRKCQ	protein kinase C theta	T-cell and NF-kappa-B activation
FCGR2A	Fc fragment of IgG receptor IIa	Ig receptor involved in phagocytosis
IL-2/IL-21	interleukin 2 and 21	mediators of adaptive and innate immunity
TRAF-6	TNF receptor associated factor 6	signal transducer
UBE2L3	ubiquitin conjugating enzyme E2 L3	targets proteins for degradation
PTPN2	protein tyrosine phosphatase, non-receptor type 2	regulator of cell growth and differentiation
NKAPL	NFKB activating protein like	regulator of inflammation
CD247	cluster of differentiation 247	part of the T-cell receptor-CD3 complex

This table includes single nucleotide polymorphisms (SNPs) in genes and in genetic regions associated with ACPA-positive or ACPA-negative patients. Some genetic associations have been observed in both groups of patients with RA; however, the association is stronger with ACPA-positive RA for most SNPs. These association studies were performed in patients of European descent and some associations might not be relevant in other ethnic groups (eg, PTPN22 in an Asian population). Furthermore, associations with several other genes may be seen in the future years. The purpose of the list is to provide current information on genes predisposing to RA and to provide an overview of the biological role of their products.

ACPA, anti-cyclic citrullinated peptide antibodies; MHC, major histocompatibility complex; RA, rheumatoid arthritis.

1.3.1 HLA association

The strongest and most relevant genetic risk factor for the development of RA, contributing around 30% to the total genetic effect, is found in the HLA class II molecule-encoding locus (chromosomal position 6p21.3). Indeed, several HLA-DRB1 molecules (*0101, *0102, *0401, *0404, *0405, *0408, *1001 and *1402) sharing a common amino acid sequence at position 70–74 in the third hypervariable region of the DR β 1 chain have been associated with an increased risk of developing RA. This common amino acid sequence has been termed the ‘shared epitope (SE)’. Many studies underline the strong association between the SE and susceptibility to, as well as severity of, RA. Individuals heterozygous for the SE have more severe and erosive disease than SE-negative patients, an effect that is further increased by homozygosity. HLA-DRB1 SE homozygotes, whether simple (having two copies of the same allele) or compound, also have a higher risk of developing extra-articular disease manifestations, including vasculitis. But perhaps the most significant recent finding concerning the SE is the realisation that, rather than being a primary risk factor for RA itself, it represents first and foremost a risk factor for ACPA positivity (table 1) (Huizinga et al, 2005*), with these autoantibodies developing preferentially (but not exclusively) in patients that harbour one or two SE alleles. Importantly, the presence of two SE alleles does not induce higher ACPA levels than the presence of only one allele, indicating a dominant effect of the SE on the immune response (van der Helm-van Mil et al, 2006). A recent study examining the risk of developing ACPA-positive RA showed that the strength of association varied according to the different susceptibility HLA-DRB1 alleles, with HLA-DR1*0404, *0405, *0408 conferring the highest risk. Furthermore, individuals carrying two susceptibility HLA-DRB1 alleles had a higher risk than those with single dose genotype (Balandraud et al, 2013). Specifically, environmental exposures, such as smoking, show an interaction with SE haplotypes and may modulate the additional risk observed in homozygous carriers of SE alleles (Lee et al, 2014; Klareskog et al, 2009).

Recently, a large-scale association study in ACPA-positive patients with RA of European descent examining 3000 single nucleotide polymorphisms (SNPs) across the major histocompatibility complex (MHC), showed that the strongest signal mapped to amino acid 11 of HLA-DRB1. After accounting for the effect of amino acid 11, an independent association was also found with two amino acids within the shared epitope sequence (amino acids 71 and 74) (Raychaudhuri et al, 2012). These results were confirmed in another study using a high-density genetic mapping with testing of more than 129 464 SNPs (Eyre et al, 2012).

Two other SNP associations within the MHC region but outside HLA-DRB1 were found. Taking into account the effect of HLA-DR β 1 amino acids 11, 71 and 74, the most significant association maps to amino acid position 9 (Asp9) of HLA-B in the class I HLA region. A second significant association was found at HLA-DPB1 in the class II HLA region, which corresponds to amino acid position 9 (Phe9). Interestingly, the amino acid positions in the HLA-DR β 1, HLA-B and HLA-DP β 1 sequences are located within the peptide-binding groove (figure 3), thus suggesting that these polymorphisms have a functional role either by shaping the T cell repertoire during

thymic selection or in peripheral immune responses. Furthermore, the presence of these polymorphisms in both class 1 and class 2 HLA regions indicates a potential role on both CD8+ and CD4+ T cells, respectively. Of note, all these polymorphisms in HLA-DR β 1, HLA-B and HLA-DP β 1 proteins almost completely explain the MHC association with RA (Raychaudhuri et al, 2012).

Figure 3 Three-dimensional ribbon models for the HLA-DR, HLA-B and HLA-DP proteins. These structures are based on Protein Data Bank entries 3pdo, 2bvp and 3lqz, respectively, with a direct view of the peptide-binding groove. Key amino acid positions identified by the association analysis are highlighted. (This figure was prepared with permission using UCSF Chimera from Raychaudhuri et al, Nat Genet 2012;44:291–6.)

1.3.2 Non-HLA association

The first robust non-HLA genetic association with RA was found during investigation of the PTPN22 candidate gene, which encodes a lymphoid-specific protein tyrosine phosphatase, Lyp, that downregulates T cell receptor signalling. A SNP at position 1858 (C->T) leads to a loss-in-function mutation that mediates its effect by destabilising PTPN22, leading to degradation by proteases. This appears to predispose to autoimmunity in general. Indeed, variations of the PTPN22 gene have also been associated with the risk of other autoimmune diseases such as type 1 diabetes, vitiligo, autoimmune thyroid disease and systemic lupus erythematosus.

Several whole genome association scans have recently been performed on large RA cohorts and healthy controls originating from different countries. Such genome-wide scans test up to 500 000 SNPs distributed over the entire genome for their association with disease. One of the most important findings of such an approach in RA is the interaction between PTPN22 risk alleles and the HLA-DRB1 SE, conferring a multiplicative risk of developing ACPA-positive RA, especially in the presence of smoking (Kallberg et al, 2007). Additionally, these scans have identified polymorphisms in genetic regions encoding a large number of protein products that may have pathophysiological relevance in RA (reviewed by Viatte et al, 2013*). Initially, polymorphisms at STAT4 were identified as new risk factors for ACPA-positive disease (Kurreeman et al, 2007; Remmers et al, 2007; Wellcome Trust Case Control, 2007). STAT4 encodes a transcription factor (signal transducer and activator of transcription 4) involved in the differentiation of type 1 helper T cells (Th1) after stimulation by interleukin (IL)-12 (discussed later). Although direct evidence for specific gene disruption by risk alleles at the other two loci has not yet been forthcoming, the most biologically compelling candidate genes remain TNF α -

induced protein 3 (TNFAIP3) and TNF receptor associated factor-1 (TRAF-1), respectively. TNFAIP3 encodes a protein (A20) that is a negative regulator of nuclear factor kappa light-chain enhancer of activated B cells (NF- κ B), a transcription factor involved in TNF α and other inflammatory responses and thus plays a part in the regulation of TNF α signalling (Plenge et al, 2007a; Thomson et al, 2007). TRAF-1 is involved in signalling of TNF α via TNFR-1 and, interestingly, downstream NF- κ B (Kurreeman et al, 2007; Plenge et al, 2007b). A potential implication of the RA association with TNFAIP3 and TRAF-1 is therefore the importance of the NF- κ B pathway in disease induction, and several additional risk loci containing NF κ B-related genes have now been identified: CD40, PRKQC and TNFRSF14 (Barton et al, 2008; Raychaudhuri et al, 2008; Criswell, 2010; Orozco et al, 2010). Functional studies are needed to confirm and further explore the mechanism of such associations.

Additional RA-associated genetic variants have been found in regions or genes encoding CTLA4, KIF5A/PIP4K2C, CCL21, CDK6, CD28, PRDM1, CD2/CD58 and IL2-RA (Barton et al, 2008; Raychaudhuri et al, 2009). It is important to note that the majority of association studies performed to date have been in Caucasian populations and some important racial differences exist in risk profiles (Viatte et al, 2012a). For example, the PTPN22 risk allele is not seen in Asian populations (Shiozawa et al, 1998), whereas, conversely, convincing evidence exists for an association of RA with a SNP in the PADI4 locus, which encodes the enzyme PAD (Suzuki et al, 2003). A recent study performed in patients with RA of European descent confirmed an association with the PADI4 locus and also with 13 new RA loci (Eyre et al, 2012). The association with the PADI4 locus was stronger amongst ACPA-positive than ACPA negative patients (table 1). It is important to mention, however, that the non-HLA genetic variants described here invariably confer only a modest independent disease risk, often displaying individual odds ratios of little more than 1. The additive effects of such minor genetic determinants are unlikely ever to describe all of the unaccounted heritability of RA and it seems likely that distinct genetic risk factors may provide multiplicative, rather than merely additive, with combined risk because of their compound molecular consequences, with gene–environment interactions further completing the picture.

Robustly validated genetic risk factors have yet to be convincingly identified for ACPA-negative RA (table 1). Some factors are associated with both ACPA-positive and -negative RA (Viatte et al, 2012b). An association with ACPA-negative RA has been found with the MHC-class II gene HLA-DR3, which is part of a conserved haplotype (A1; B8; DRB1*03) that includes the MHC class III region, itself comprising many immune-related genes. In addition, polymorphisms defining several haplotypes in the promoter region of the gene coding for IRF5 (interferon regulatory factor 5) were found to be associated with ACPA-negative RA. IRF5 is involved in signalling via Toll-like receptors 7 and 9 and the polymorphisms might influence the induction of IRF5-dependent type I interferons (Sigurdsson et al, 2007). One partial explanation for the relative lack of identified risk factors for ACPA-negative RA is the challenge of recruiting sufficient numbers of well-ascertained patients into studies and the potential heterogeneity in this group of patients defined by the absence of a specific

autoantibody. Nevertheless, family-based studies do show that the degree of heritability is similar between the two subtypes, indicating that additional, as yet unidentified genetic factors must exist that predispose to ACPA-negative RA (van der Woude et al, 2009).

1.3.3 Smoking, genes, ACPA and other autoantibodies

Cigarette smoking is the most important environmental risk factor for RA. Several years of smoking confer an increased risk of the disease and are associated with more severe disease, with the risk increasing in proportion to the number of pack-years (Ostergaard et al, 2003a). Importantly, and analogous to the case with SE and PTPN22 risk alleles described above, smoking is seen to represent a risk factor for ACPA-positive, but not ACPA-negative, RA.

Indeed, this risk is further increased in the presence of SE alleles (up to an estimated 21-fold as compared with SE-negative non-smokers), illustrating the multiplicative effect of combined risk factors (Klareskog et al, 2006*; Kallberg et al, 2007). The combinatory effect of cigarette smoke and genetic factors (SE and PTPN22) has been predominantly observed for some specific ACPA, including anti-citrullinated α -enolase and anti-citrullinated vimentin (Lundberg et al, 2013) (table 2). The mechanism by which smoking may induce anti-citrulline immune responses has been investigated in smokers and non-smokers. The results showed that protein citrullination was present in a higher percentage of bronchoalveolar lavage cells of smokers than of non-smokers. Thus, it is plausible that enhanced protein citrullination and local inflammation may favour specific immune responses against citrullinated autoantigens in genetically susceptible individuals. However, how and why this response eventually targets the joints, remains unknown, although the participation of additional environmental factors is probably required.

It has become increasingly clear that ACPA status delineates two pathophysiologically distinct subsets of a similar clinically defined phenotype. Current classification criteria therefore include ACPA as one – but obviously not the essential feature for RA. The pathogenesis of autoantibody-negative disease is less clear. Importantly, other autoantibodies may exist in the absence of RF and ACPA, and the more recently discussed anti-carbamylated protein (CarP) antibodies may be one of these (Shi et al, 2011). Like citrullination, carbamylation is a post-translational modification by which lysine residues in a given protein are non-enzymatically converted into homocitrulline in the presence of cyanate. Although trace amounts of carbamylated proteins were detected in healthy individuals (suggesting that carbamylation is a physiological process), excess of carbamylation has been described in three states of cyanate abundance: inflammation (generation of cyanate from thiocyanate and hydrogen peroxide by myeloperoxidase (MPO)), cigarette smoking (direct inhalation of cyanate) and uraemia (abundance of urea as a source of cyanate) (Shi et al, 2014). As in the case of citrullination, an array of proteins is expected to be carbamylated in inflamed joints, although the exact identity of targeted proteins is yet to be explored (Prujin et al, 2015).

Anti-CarP antibodies were detected in the serum of over 40% of patients with RA (IgG in 45% and IgA in 43%). Despite their partial overlap with the presence of ACPA, it is noteworthy that about 16% of ACPA-negative patients harboured anti-CarP IgG antibodies and 30% displayed anti-CarP IgA antibodies (Shi et al, 2011). Such a finding narrows the percentage of “true seronegative” RA patients, especially given that anti-CarP antibodies seem to display prognostic features similar to those of ACPA (Trouw et al, 2012). The presence of anti-CarP antibodies at baseline was associated with more severe radiological damage. Unlike their IgA isotype, this role of the anti-CarP IgG isotype remained even after correcting for ACPA and RF positivity (Shi et al, 2011). Anti-CarP were also detected in patients with arthralgia in the absence of signs of arthritis and their presence predicted the development of RA independently of ACPA (Shi et al, 2013). Future studies will have to show the diagnostic and prognostic value of these new autoantibodies.

In addition to citrullination and carbamylation, malondialdehyde-acetaldehyde (MAA) adducts have recently been described as the third post-translational modification class serving as a target of antibodies in patients with RA (Thiele et al, 2015). MAA are produced during oxidative stress typically caused by inflammation. The presence of anti-MAA antibodies was associated with ACPA and RF positivity, but anti-MAA did not cross-react with these antibodies (Thiele et al, 2015). Interestingly, neutrophils have been identified as a site where all of the three post-translational modifications take place (Darrah and Andrade, 2015). However, the role of anti-MAA antibodies, as well as the possible mechanistic link of the three modification classes require further elucidation.

1.4 Additional environmental risk factors

Scope for additional robust gene–environment interactions to be found in the aetiology of RA remains, but that of smoking in relation to the SE is the only one discovered to date (table 3). In RA, some environmental factors may have specific effects directly related to RA pathogenesis (as suggested for smoking), whereas others might have non-specific effects promoting inflammation in general (eg, triggers of innate immunity). Thus, the former will only be relevant for subtypes of RA (eg, ACPA-positive RA), whereas the latter will influence the disease in a broader sense.

Coffee consumption has shown association with RA in several cohorts, although stratification for smoking usually reduced the significance of this finding. In a Danish cohort, however, coffee consumption did show an association with ACPA-positive RA after adjustment for smoking. A recent meta-analysis of nine studies showed that alcohol intake was inversely correlated with the development of ACPA-positive RA, but had no significant effect on ACPA-negative RA (Scott et al, 2013). Occupational exposure to mineral oils (eg, motor oils, hydraulic oils, etc.) was found to be a risk factor for ACPA-positive RA in men in a Swedish cohort,

*Adjusted for age, gender, residential area.

This case–control study provides the odds ratio (OR) for development of CEP-1 and Cit-vim ACPA in the presence of tobacco smoke or SE, or PTPN22 or various combinations thereof. The OR of having CEP-1 and/or Cit-vim (24.4, 11.5 or 50.1) were significantly higher in smoking subjects who were positive for SE and PTPN22.

Specific ACPA, anti-cyclic citrullinated peptide antibodies, assessed here were; CEP-1, anti-citrullinated α -enolase (CEP-1); Cit-vim, anti-citrullinated vimentin; SE, shared epitope.

Table 3 Environmental factors and development of RA

Predisposing factors	Protective factors
Tobacco smoke (ACPA+)	Alcohol consumption (ACPA+)
Periodontal disease (<i>P. gingivalis</i>) (ACPA+)	Younger age at menarche (≤ 12)
Coffee consumption (ACPA+)	
Exposure to mineral oils (ACPA+)	
Silica dust + tobacco smoke (ACPA+)	
Older age at menarche (≥ 15)	
Pregnancy*	

*Increased rate of RA onset 1 year after delivery. Multiparity (>3) favours a more severe course, whereas contraceptive use decreases RA severity, neither of them influence the development of RA.

ACPA, anti-cyclic citrullinated peptide antibodies; RA, rheumatoid arthritis.

independent of the presence of shared epitope alleles. This finding is of interest, as mineral oils are arthritogenic in certain rat strains due to a yet unknown mechanism (Bartfai et al, 2007). A study performed in the Malaysian population showed that professional exposure to silica was associated with increased risk of developing ACPA-positive RA. Notably, the risk was particularly high in cigarette smokers exposed to silica dust, thus emphasising the combination between two environmental factors inducing lung inflammation (Yahya et al, 2013).

Infections are major candidates for the induction of autoimmunity and have, therefore, been intensively studied also in RA. Although there is still no pathogen-derived antigen clearly linked to RA pathogenesis, the interplay between the human microbiome (especially in the oral cavity, the gut and lungs) and the host's immune system is being increasingly investigated. A shift from a normal symbiotic towards a “dysbiotic” microbiome, characterized by overgrowth of pathogenic and a lack of commensal bacteria, may be responsible for changes in the innate and adaptive immunity responsible for the development of RA (Sandhya et al, 2016). The presence of periodontal disease has been reported in different reports as an increased risk factor of developing RA. It is particularly interesting to note that *Porphyromonas gingivalis*, one of the micro-organisms involved in periodontal disease uniquely expresses a bacterial form of peptidylarginine deiminase (PAD) and enolase. *Porphyromonas gingivalis* PAD can citrullinate different peptides in vitro and can thus, generate self-antigens. PAD can also be autocitrullinated, and antibodies against PAD have been detected in patients with RA (Scher et al, 2014). Furthermore, anti- α -enolase antibodies cross-react with recombinant bacterial citrullinated enolase suggesting that *Porphyromonas gingivalis* infection can induce autoimmune responses in susceptible individuals by ‘molecular mimicry’. Notably, antibodies against *Porphyromonas gingivalis* were detected in autoantibody (ACPA and RF) positive individuals at risk of developing RA (first-degree relatives of patients with RA) (Mikuls et al, 2012). Together, several data indicate that periodontal disease, particularly in

the presence of *Porphyromonas gingivalis*, is probably associated with an increased risk of developing RA, even more pronounced in smokers (table 3). Furthermore, there is evidence suggesting that smoking may be associated with translocation of supraglottic bacteria, species such as *Prevotella* and *Porphyromonas*, to the lungs, leading to increased activity of PAD and airway inflammation (Sandhya et al, 2016).

Alterations of the gut microbiome (observed through its “window” – the stool microbiome) have also been described in patients with RA, offering new insights in the complex relationship between pathogens and commensals on one side and the host’s immune system on the other. An abundance of *Prevotella copri* with loss of *Bacteroides* has been demonstrated in the stool of patients with new onset RA (Scher et al, 2013). Another study demonstrated fewer *Bifidobacterium*, bacteria of the *Bacteroides-Porphyromonas-Prevotella* and the *Eubacterium rectale-Clostridium coccoides* groups of patients with RA compared to those with non-inflammatory fibromyalgia (Vahtovuo et al, 2008). Interestingly, the gut and oral dysbiosis were shown to correlate with each other and with laboratory measures such as the CRP, RF and anti-CCP antibodies in a recent metagenomics study of RA patients; the same study also demonstrated a partial resolution of the dysbiosis after treatment with DMARDs (Zhang et al, 2015). Despite these findings and evidence based on animal studies, a beneficial effect of probiotics has not been unequivocally demonstrated in the treatment of RA. *Lactobacillus casei* has been the only probiotic the effect of which has been revealed both on disease activity and levels of inflammatory mediators in a randomized trial (Vaghef-Mehrabany et al, 2014). However, the effect is probably strain- and dose-specific and this finding is not sufficient to recommend the routine use of probiotics in RA.

Female predominance in various autoimmune diseases, including RA, suggests that sex hormones and reproductive factors influence both RA development and severity. Women with lower age at menarche have a comparatively low risk for the development of RA. In the Danish cohort, for example, women with older age at menarche (≥ 15) had an almost twofold risk of developing RA as compared with women aged ≤ 12 years at menarche. Pregnancy is in itself a risk factor for the development of RA, as around 12% of women with RA experience disease onset within 1 year after pregnancy. During pregnancy, most women with RA (in older studies up to 90%) experience a significant reduction in disease activity (including complete remissions), but almost all patients relapse within 3 months after delivery (table 3)(Ostensen and Villiger, 2007). Multiparity (>3 children) favours a more severe course of disease, but does not additionally increase the risk for developing RA. Use of oral contraceptives, on the other hand, lowers disease severity, but data from initial studies showing a protective effect on RA development could not be confirmed after adjustment for age (Jorgensen et al, 1996; Sverdrup et al, 2005; Pedersen et al, 2006).

1.5 Epigenetic modifications

Epigenetic modifications take into account all the changes in chromosomal regions that do not affect the DNA sequence, but include DNA methylation and covalent histone modifications such as acetylation, deacetylation, methylation and ubiquitination. All these changes will alter the accessibility to the transcriptional machinery, thus influencing gene expression. A wide range of environmental exposures can alter the epigenome—for example, cigarette smoke can decrease DNA methylation. Epigenetic changes can be inherited during cell mitosis, and stochastic epigenetic instability can also occur over time in multiple cell types without any obvious stimulation. Most research has focused on the role of DNA methylation. Methylation of cytosine residues at the carbon 5 position occurs primarily in CpG rich regions, known as CpG islands on gene promoters in the vicinity of transcriptional start sites. DNA methylation is associated with gene silencing and is regulated by DNA methyl transferases. Histones are proteins that act as spools for DNA. For effective transcription this condensed chromatin structure needs to be loosened. Histone acetylation on lysins (through histone acetyl transferase, HAT) weakens the interaction between histones and DNA, and thus promotes transcriptional activity; vice versa, deacetylation of histones (through histone deacetylases, HDACs) strengthens these interactions, which thus leads to suppression of transcription. Histone methylation can lead to transcriptional activation or repression and histone ubiquitination can also alter gene transcription.

Several of these epigenetic modifications may affect the expression of cytokines, chemokines and matrix metalloproteinases (MMPs) in RA (reviewed by Klein and Gay, 2013). Synovial fibroblasts from patients with RA display a different DNA methylation signature than those of patients with osteoarthritis. Notably, an altered methylation of genes encoding different cytokines has been described in RA peripheral blood mononuclear cells and synovial fibroblasts. HDACs are differentially expressed in RA synovial cells and have been shown to regulate the expression of cytokines such as TNF and IL-1. Overexpression of sirtuin 1, a member of the HDAC family, promotes cytokine production by monocytes and RA synovial cells and inhibits apoptosis (Niederer et al, 2011). Of note, the expression of HDAC can also be altered by stimulation of synovial fibroblasts with TNF (Kawabata et al, 2010). Finally, in addition to histones, a growing number of other intracellular molecules are targets for acetylation, including transcription factors, signalling molecules and structural proteins. It has been shown that HDACs act on all these different targets to regulate autoimmune manifestations and HDAC inhibitors are the best studied epigenetic therapeutic agents. The anti-inflammatory properties of these compounds include reduction of cytokine levels (Bosisio et al, 2008) and increased Foxp3+ regulatory T cell function (Beier et al, 2012). The use of an HDAC inhibitor ameliorated joint inflammation and prevented structural damage in different models of arthritis (Joosten et al, 2011) and thus, might represent an interesting therapeutic approach for RA.

1.6 Disturbances of the immune system

The heritability of RA, together with the presence of autoantibodies that precede clinical onset in a subset of patients, supports a now widely held pathogenetic model in which autoimmune propensity is long established by the time joint inflammation is ‘triggered’. The following sections review the different cell types involved in the pathogenesis of RA during the preclinical phases before the development of RA and in the joints during established RA (figure 4).

1.6.1 *T cells*

T cells are one of the most abundant cell types in RA synovium, comprising 30–50% of synovial tissue cells. The majority are CD4+, Th cells, matured from naïve precursors, which can be divided into different subsets, including Th1, Th2 and Th17 cells, according to the patterns of cytokines that they produce and their role in host defence. Th1 cells produce mainly interferon (IFN) γ and play a major role in controlling infections with intracellular micro-organisms (ie, *Mycobacterium tuberculosis* and viruses). Th2 cells produce mainly IL-4, IL-5 and IL-13 and play a critical role in the defence against parasitic infections. Th17 cells produce IL-17, IL-22 and granulocyte-macrophage colony stimulating factor (GM-CSF) and activate immune responses against extracellular bacteria and fungi. The responses of different innate immune cells that act as effectors in the control of infection (e.g. macrophages, eosinophils and neutrophils) to the cytokines produced by these different types Th cells are referred to as Th1, Th2 and Th17 responses, respectively. Naïve Th cells (Th0) are polarised into these different subsets according to the cytokine ‘milieu’ present during their activation by antigen-presenting cells. Classically, IL-12 induces the polarisation of Th1 cells, IL-4 stimulates the polarisation of Th2 cells and transforming growth factor β in combination with IL-6 polarises Th0 into Th17 cells. In addition, IL-1 β and IL-23 also play an important role in the generation of Th17 cells. Master transcription factors are associated with the different Th subsets, including T-bet for Th1, GATA-3 for Th2 and ROR γ T for Th17 cells. In addition to their role in the control of infection, Th cell subsets are also associated with specific immunopathological manifestations: Th1 cells in cell-mediated autoimmune diseases and Th2 cells in allergic conditions. Th17 cells have been shown to be involved in the pathogenesis of several experimental models of autoimmune diseases (figure 5). Th17 cells are critical orchestrators of collagen-induced arthritis in mice (Murphy et al, 2003), and evidence for their importance in human RA comes from the observation that both IL-17 and IL-23 are found in serum samples, synovial fluid and synovial biopsy specimens of patients, but are mostly absent from the same compartments in osteoarthritis. IL-17 itself is highly pleiotropic, acting on a variety of cell types to perpetuate local inflammation while promoting angiogenesis, osteoclastogenesis and, ultimately, the destruction of cartilage and bone. Ironically, in contrast to the – partly impressive – clinical effects in psoriasis, psoriatic arthritis, and ankylosing spondylitis, the clinical trials of IL-17 inhibitors in RA have been disappointing (Smolen et al., Lancet 2016). The first IL-17 inhibitors have been approved for psoriatic arthritis and axial spondylopathies in 2015.

Figure 4 Suggested mechanism of the development of the immune response in RA. Antigen-specific T cell activation by DC–T cell interaction usually occurs in lymph nodes. Naïve T cells thereby differentiate into effector T cells that give help to B cells, which leads to production of autoantibodies (eg, anti-cyclic citrullinated peptide antibodies, and others). These antibodies then form immune complexes, accumulate in joints, and activate complement. This leads to recruitment of effector cells (macrophages, neutrophils, etc.), which secrete proinflammatory cytokines and chemokines and activate osteoclastogenesis. AB, autoantibody; DC, dendritic cell; IFN, interferon; IL, interleukin; RANKL, receptor activator of the NF- κ B ligand; TNF, tumour necrosis factor. (Adapted from Luross et al, *Immunology* 2001;103:407–16.)

Two other Th cell subsets may polarise after antigen-experience, which also play important roles in immune responses—namely, follicular helper T cells (Tfh) and regulatory T cells (Tregs). Tfh are located in the periphery within B cell follicles of secondary lymphoid organs (e.g. lymph nodes, spleen, Peyer's patches). By their close contact with B cells they contribute to class switching and affinity maturation. They secrete IL-21 and also other cytokines (IFN γ and IL-4) and their master transcription factor is Bcl-6. Tregs play a critical role in

immune suppression and tolerance in autoimmunity. These cells also regulate inflammation and adaptive immune responses. Tregs are produced either in the thymus and termed natural Tregs, or in the periphery and known as induced Tregs (iTregs). They both have the transcription factor Foxp3 in common. Transforming growth factor β stimulates the polarisation into iTregs. Although Tregs are present in large amounts in the joints of patients with RA, these cells have an impaired suppressive function. TNF α in the synovial fluid has been shown to participate in the functional Treg defects (Ehrenstein et al, 2004). Recently, the molecular mechanism involved in the inhibitory effect of TNF α on Treg activity has been characterised. TNF α -induced dephosphorylation of the Foxp3 DNA-binding domain leads to the impairment of Foxp3 transcriptional activity and Treg function. This effect is dependent on the enzyme protein phosphatase 1, the expression of which is stimulated by TNF α (Nie et al, 2013).

Figure 5 The cytokine ‘milieu’ influences the polarisation of Th0 cells into different Th subsets, including Th1, Th2 and Th17 cells. These T cells express distinct cytokines and transcription factors. The cytokines produced by different Th cells recruit and stimulate different innate effector cells, including macrophages, eosinophils and neutrophils (Th1, Th2, or Th17 “responses”, respectively). These different Th responses are involved in the protection against microorganisms (in black) and also in different immunopathological conditions (in red). GM-CSF, granulocyte-macrophage colony stimulating factor; IFN, interferon; IL, interleukin; TGF, transforming growth factor.

For efficient effector T cell maturation, the recognition of antigen by naïve T cells in the context of MHC molecules requires additional costimulatory signals, without which T cells become anergic. Interaction of surface-expressed CD28 (T cells) and CD80/86 (antigen-presenting cells) generates one of the most important of these co-stimulatory signals, with excessive signalling normally controlled by T cell derived CTLA-4, which is therefore an important “immune checkpoint”: when bound to CD80/86 (instead of CD28) it off regulates the co-stimulatory signal and T-cell activation. The exploitation of this mechanism using abatacept (CTLA4-Ig fusion protein) is now an established treatment option: the therapeutic efficacy of CTLA4-Ig (abatacept) provides perhaps the most compelling evidence that these cells are important drivers of RA, although its effects are still not fully understood, and there might off-target effects of this compound, or simply retrograde effects affecting the monocyte/macrophage and not (only) the T-cell (Bonelli et al, 2013).

1.6.2 B cells

The importance of B cells in RA pathogenesis has only recently been appreciated. The realisation that circulating autoantibodies often predate arthritis onset by many years implicates early involvement of autoantigen-specific B cell activation and plasma cell differentiation. The frequent occurrence of germinal centre-like structures in RA synovium, ideally suited to humoral immune responses, along with the recognition that B cells can themselves present antigenic peptides (even priming naïve T cells in some cases (Edwards and Cambridge, 2006)) has made the case for their role in the pathology (Dorner, 2006). This is borne out by the success of therapeutic B cell depletion using, for example, rituximab.

During inflammation, B cells infiltrate RA synovium, although the degree of infiltration and local structural organisation varies significantly between patients. Fibroblast-like synoviocytes and dendritic cells in synovium secrete factors which attract B cells and influence their differentiation and survival and, in some patients, orchestrate the formation of tertiary lymphoid structures, which themselves perpetuate autoimmunity. These factors include BAFF, CXCL12, CXCL13 and APRIL, some of which are currently being evaluated as therapeutic targets.

Far from being mere ‘antibody producers’, accumulating evidence assigns key roles to B cells in many aspects of immune functions. B cells can take up antigen via surface immunoglobulin and are efficient antigen-presenting cells. Moreover, recent evidence suggests that immunoglobulin class switching and somatic hypermutation, which are classically dependent on CD40–CD40L interactions with CD4+ T cells, may also occur independently of T cells. This process again requires BAFF, which is present in increased amounts in RA synovium and additionally prolongs B cell survival (Dorner, 2006; Mauri and Ehrenstein, 2007). B cells are also prolific producers of cytokines. By secreting TNF α and IL-6, they contribute to the activation of macrophages and directly participate in inflammation. IL-6 is also an important autocrine differentiation factor for B cells.

1.6.3 Monocytes/macrophages

Activated macrophages in RA synovium are central to driving and maintaining chronic inflammation. Macrophages are multipotent effector cells that efficiently integrate innate and adaptive immune responses. They are abundantly present in the rheumatoid synovial membrane and at the cartilage–pannus junction. Important functions include strong phagocytic activity, antigen processing and presentation, expression of Fc receptors responsive to (auto-) antibodies and immune complexes, complement activation and regulation, Toll-like receptor expression and tissue degradation and remodelling. As macrophages reside in tissue in most organs they are, together with dendritic cells, likely to be the first to encounter pathogen-derived antigen and are well placed to present it to autoreactive T cells, providing the initial trigger necessary to start an immune response on the basis of genetic predisposition. Macrophages are important producers of proinflammatory cytokines (eg, TNF α , IL-1, IL-6), cartilage-degrading enzymes (MMP-9 and MMP-12) and growth factors (GM-CSF), among other mediators of pathology. The relative importance of these various macrophage functions during the course of the disease may change over time (Kinne et al, 2007). With such a central role in the disease process, it is perhaps not surprising that expression of the CD68 macrophage surface marker has shown promise as an early biomarker for drug responsiveness in RA (Chomarat et al, 1995). Indeed, most of the currently used agents effective in RA have been shown to decrease the number of CD68 positive macrophages in the synovial sublining: prednisone, methotrexate and leflunomide, as well as biologics such as infliximab and rituximab (Cascao et al, 2015). Furthermore, a decline in disease activity has also been associated with this effect (Haringman et al, 2005).

1.6.4 Mast cells

Mast cells are highly granular cells best known for their role in allergy and anaphylaxis, as components of the innate immune system. They may be stimulated to degranulate in response to direct injury. Once activated, the many mediators released by mast cells appear to act in concert, driving neighbouring immune cells towards an inflammatory phenotype, promoting angiogenesis and, both directly and indirectly, degrading cartilage. Also, a potentially crucial role for mast cells has been discovered as producers of IL-17 (Maruotti et al, 2007).

1.7 Synovial histopathology

The normal synovium consists of a cellular lining layer in direct contact with the synovial fluid and a sublining layer underneath the lining. The lining is a one to four-cell thick membrane comprised of macrophage-like and fibroblast-like synoviocytes (MLS and FLS, respectively). The sublining is a loose connective tissue composed of extracellular matrix, fibroblasts, macrophages, blood and lymph vessels, as well as nerve fibres (Barland et al, 1962). Both layers undergo changes in inflammatory arthritis. The lining becomes up to 15 cells thick, with ultrastructural changes of FLSs (enlargement of the rough endoplasmic reticulum, Golgi apparatus and

lysosomes) suggestive of increased metabolic activity. The sublining hosts an inflammatory infiltrate consisted of T and B lymphocytes, plasma cells, macrophages and - to a lesser extent - dendritic cells, mast cells, natural killer cells and more rarely, neutrophils, which are predominantly present in the synovial fluid (Kiener and Karonitsch, 2011). Three distinct histological patterns have been recognized in chronic synovitis of RA. The most common is a diffuse inflammatory infiltrate including lymphocytes and macrophages. The second pattern is characterised by the presence of lymphoid follicles. In some cases the lymphoid follicles become organised with germinal centres similar to those of secondary lymphoid organs such as in lymph nodes and can be considered as tertiary lymphoid organs. The third and rarest form of synovitis includes the presence of granulomas resembling rheumatoid nodules (Weyand and Goronzy, 2003). The first histological pattern has been associated with a milder course of the disease. Apart from this classification, histological differences have been described between early and long-standing disease: biological processes involving T cells, granulocytes, the cell cycle and macrophages seem to be associated with late rather than early disease (Lequerre et al, 2009).

In addition to hyperplasia of the lining and accumulation of the inflammatory infiltrate, neoangiogenesis is the third histological hallmark of synovitis of RA. Despite a more pronounced vascularization in SpA compared to RA, routine synovial histology does not allow to discern between the major types of arthritis. More sophisticated molecular methods may serve this purpose, but they still require validation (van de Sande and Baeten, 2016).

The examination of synovial characteristics in patients with RA with and without ACPA resulted in conflicting data. Some authors observed a higher number of infiltrating lymphocytes in ACPA-positive patients, whereas ACPA-negative patients had more extensive fibrosis (van Oosterhout et al, 2008). However, these findings were not confirmed by subsequent studies (Gomez-Puerta et al, 2013) and an association of histological patterns and distinct clinical subsets has not yet been confirmed.

Insight into the molecular pathways involved in the rheumatoid synovium has emerged recently using whole genome-wide analysis of gene expression. These studies showed considerable molecular heterogeneity. Some subsets exhibited genes associated with predominant macrophagic infiltration or with the presence of lymphoid infiltrates and lymphoid follicle-containing synovial tissue. Alternatively, expression of genes involved in matrix remodelling was detected in synovial samples with low inflammation and predominant fibrous tissue (van Baarsen et al, 2009). The presence of a few predictive markers of response to TNF antagonists has been identified in large expression studies (Lindberg et al, 2010). A recent whole genome expression study identified intercellular adhesion molecule 1 (ICAM1) and C-X-C motif chemokine 13 (CXCL13) as predictive markers of response to adalimumab (anti-TNF antibody) and tocilizumab (anti-IL-6R antibody), respectively. These data were confirmed using the serum levels of soluble ICAM1 and CXCL13 from patients who participated in a head-to-head clinical trial comparing the efficacy of adalimumab and tocilizumab in

monotherapy (Dennis et al, 2014). These results indicate that the heterogeneity in synovial tissue infiltrates and their associated molecular signatures may be useful for predicting the therapeutic response. In that context, it seems that RA patients with a “pauci-immune” phenotype of low-grade synovial inflammation are less prone to a favourable response to TNF- α inhibitors (Townsend, 2014). In general, these markers and putative specific histopathological subtypes have been proposed as guidance for therapeutic decision making in RA (Astorri et al, 2015), but are still controversial regarding their practical meaningfulness.

1.8 Cartilage and bone degradation: the role of fibroblasts and osteoclasts

Changes in the synovium of chronic RA result in the formation of the pannus – synovium remodelled into an inflammatory tissue invading the adjacent cartilage and subchondral bone (Kiener and Karonitsch, 2011), being responsible for the development of bone erosions and irreversible damage. The process of cartilage and bone degradation is initiated in the mineralized cartilage close to the junction between synovium and the joint end (Hayer et al, 2007), given that this type of cartilage is particularly susceptible to bone resorption mediated by osteoclasts (Schett, 2007).

Two cell types are of prime importance for destruction of cartilage and bone. Synovial fibroblasts adhere to cartilage and degrade extracellular matrix. Osteoclasts, on the other hand, are mainly involved in bone destruction. Both cell types closely interact with cells of the immune system and, by secreting large amounts of cytokines, themselves help to maintain inflammation. Synovial fibroblasts in RA are characteristically found in the sublining layer of the synovium. Expression of various transcription factors indicates that they proliferate locally in disease, contributing to synovial hyperplasia. Functionally, they adhere to cartilage and display an aggressive invasive behaviour. Synovial fibroblasts are an abundant source of cytokines and chemokines such as IL-15, IL-16, CXCL12, CXCL13, BAFF and members of the IL-6 family (eg, IL-11). These cytokines activate T cells and influence B cell migration and survival. Large amounts of secreted prostaglandin E2 additionally support inflammation. In addition, degradation of cartilage by synovial fibroblasts is due to the secretion of MMPs and cathepsins. Specifically, synovial fibroblasts produce MMP-1, -3, -13, -14 and -15 as well as cathepsins B, K and L. These enzymes degrade extracellular matrix, providing a rich source of potential neoantigens for T and B cell polyclonal proliferation (Karouzakis et al, 2006).

Bone degradation in RA is mainly mediated by osteoclasts (figure 6). Osteoclastogenesis—that is, the differentiation of osteoclasts from precursor cells, requires M-CSF and RANKL (receptor activator of the NF- κ B ligand), a molecule first identified in activated T cells (Sato and Takayanagi, 2006). Meanwhile, RANKL has been found in RA synovium. RANKL is expressed by T cells, which thereby directly drive osteoclastogenesis (Toh and Miossec, 2007), and also by neutrophils and in large amounts by synovial fibroblasts (Poubelle et al, 2007). TNF α accelerates this process by inducing RANKL expression and enhancing RANKL signalling. Interestingly,

Th1- and Th2-cytokines (IFN γ , IL-4, IL-10) as well as IL-12 and IL-18 inhibit osteoclastogenesis, whereas IL-17 induces RANKL expression in osteoblasts.

Figure 6 Factors contributing to osteoclastogenesis. Macrophages, synovial fibroblasts and T cells express IL-1, TNF α and RANKL, factors important for differentiation of osteoblasts to osteoclasts. Multinucleated osteoclasts degrade bone, thereby creating radiographically detectable erosions. IL, interleukin; RANKL, receptor activator of the NF- κ B ligand; TNF, tumour necrosis factor.

Summary points

- Rheumatoid arthritis is a heterogeneous disease with a polygenetic background, that typically, but not always presents with autoantibodies (including ACPA and RF, anti-CarP etc.).
- The presence of ACPA and RF and rising C-reactive protein (CRP) levels years before onset of clinical symptoms indicate that relevant immune responses for RA development are initiated very early.
- High titer RF (>45UI) and positive ACPA are highly and similarly specific for RA; low positive RF can also be found among healthy (elderly) individuals and patients with other autoimmune diseases.
- The most important genetic risk factor for RA development resides in the MHC class region and includes polymorphisms in HLA-DR (including the shared epitope alleles), HLA-B and HLA-DP genes. These predisposing MHC alleles are particularly associated with the development of ACPA-positive RA.
- Smoking is thus far the most important environmental risk factor associated with the development of RA. Similar to shared-epitope alleles, smoking is a risk factor only for ACPA-positive RA.
- CD4+ T cells (also termed T helper cells) consist of different subsets (Th1, Th2, Th17, Tfh, Tregs). Th17 cells might be more crucially involved in RA and other autoimmune diseases, and efficacy of B cell depleting therapy and the ACPA response indicate that B cells are more relevant than previously expected.
- RA development requires several factors acting at different times in an orchestrated manner.
- Epigenetic changes, such as DNA methylation and histone acetylation, are present in immune cells and stromal cells (synovial fibroblasts) of patients with RA and may contribute to the pathogenesis of the disease. Treatments targeting histone deacetylases have shown some promising results in preclinical models of arthritis.

2 Clinical aspects of RA

2.1 Introduction

Rheumatoid arthritis (RA) is the most prevalent chronic inflammatory joint disease. No single clinical sign, symptom or test reliably distinguishes it from other joint diseases, and the pathological features of synovitis, the hallmark of RA, are not unique. Rather, the diagnosis of RA is based on a combination of clinical findings, laboratory tests and imaging. RA is a heterogeneous condition with a variable mode of disease onset and disease course. Some patients have a very acute disease onset with fever, polyarthritis and extra-articular manifestations, whereas other patients have a more gradual and insidious onset. The latter presentation is more common. Typical articular signs and symptoms include pain, stiffness and swelling. Redness and warmth of affected joints are less common findings. Concomitant tenosynovitis, bursitis and even carpal tunnel syndrome may be present. RA is a systemic disease as may be manifested by generalised weakness, weight loss or low-grade fever and extra-articular features such as sicca syndrome, nodules and interstitial lung disease.

A particular type of early RA characterised by episodic attacks is known as 'palindromic rheumatism'. The clinical picture includes variable episodes of polyarthritis, which suddenly affect one or more large or peripheral joints. The duration varies from a few hours to a few days, followed by spontaneous improvement and complete disappearance of all rheumatic signs between attacks. About one-third of these palindromic cases will eventually evolve into typical RA.

Both prevalence and incidence rates of RA are about two to four times higher in women, and symptoms are more severe than in men (Kvien et al, 2006). The female/male ratio decreases with age. The reasons for the greater prevalence of RA among women have not been firmly established. A decline in the incidence of RA over recent decades has been reported in a number of countries (eg, Finland, England/Wales, United States and Japan). The decreasing incidence has been especially apparent in women, possibly as a consequence of some environmental factor such as the introduction of oral contraceptives in the 1960s (Heiberg et al, 2005). A shift in the incidence towards a higher age at disease onset has been observed across several cohorts. The incidence rate seems to increase with age up to a plateau around the age of 60 (Symmons et al, 1994).

2.2 Disease onset

2.2.1 Articular manifestations

The typical joint involvement at disease onset is swelling of the proximal interphalangeal (PIP) joints, the metacarpophalangeal (MCP) joints, the wrists (figure 7) and the metatarsophalangeal (MTP) joints. However, the disease may also start gradually with involvement of one or a few joints and then over time develop from

an undifferentiated oligoarthritis or polyarthritis into a more polyarticular and classically symmetrical disease. Occasionally, the disease may present with a monoarthritis, for example of the knee.

Figure 7 *Symmetrical swelling of the proximal interphalangeal joints and the metacarpophalangeal joints, typical of rheumatoid arthritis.*

2.2.2 Extra-articular manifestations

The dominating feature at disease onset is usually joint involvement. However, the disease may start much more dramatically with fever and inflammatory manifestations of internal organs—for example, with pericarditis or pleuritis. In such cases, other systemic diseases may be the most important differential diagnoses, such as systemic lupus erythematosus. Other extra-articular manifestations such as sicca syndrome, vasculitis, nodules, bronchial dilatation and interstitial lung fibrosis are more commonly seen in established seropositive RA. For more detail see section 2.4.7, 'Extra-articular manifestations and RA-related comorbidities'.

2.2.3 Symptoms

The symptoms of the patient will typically reflect the most prominent disease manifestations at disease onset. Joints with inflammation are painful, tender and the patient perceives stiffness on movement. The patients may also find that the joints are swollen. Morning stiffness is common and generally exceeds 30 min. Other frequently occurring general symptoms include fatigue and loss of energy.

2.2.4 Clinical findings

The typical clinical finding of inflamed joints is soft tissue swelling and tenderness (figure 8) and is often associated with a limited range of motion. The ‘squeeze test’ across the MCP and MTP joints has been considered a useful screening technique to detect synovitis of the respective joint regions (figures 9a and 9b). Detection of synovitis is essential for the diagnosis (figures 9–11). Swelling of the finger joints will generally be symmetrical, as is also the case for the middle-sized joints, such as the wrists and the mid-foot. Involvement of shoulders and hips at disease onset is rare.

According to the 2010 ACR/EULAR criteria, definite clinical synovitis in at least one joint assessed by clinical evaluation (i.e. palpation) is a minimum prerequisite for a classification attempt (Aletaha et al, 2010). In other words, the classification criteria should not be used on patients with tender but no swollen joints (arthralgia without arthritis). At the same time, the “squeeze test” is a classical screening method for inflammatory joint disease, based on the hypothesis that joint tenderness in patients with early arthritis may be a harbinger of subclinical inflammation. However, the squeeze test itself was clinically correlated with tenderness, and not with swelling (Wiesinger et al, 2013). Despite being recommended as a part of the early referral (screening) algorithm for newly diagnosed RA (Emery et al, 2002), both the MCP and MTP “squeeze tests” have demonstrated a rather low sensitivity (53% and 54%, respectively), and only a moderate specificity (82% and 74%) for identification of arthritis – up to 50% of swollen MCPs and MTPs were missed by the test (van den Bosch et al, 2015). Since the “squeeze test” still remains a quick and inexpensive method, it may be considered in the screening algorithm, but in conjunction with the more thorough approach including tender and swollen joint counts.

Figure 11 Detecting proximal interphalangeal joint swelling; four-finger technique, alternating compression with the left and right hands.

Figure 12 Detecting wrist synovitis.

The clinical examination should include a general physical examination as extra-articular manifestations may be present. Patients with suspected serositis should be examined for clinical signs of pericarditis and pleuritis. Bibasilar inspiratory crepitations can point to underlying interstitial lung disease. Splenomegaly should be sought in the setting of Felty's syndrome. A general organ examination is also important for the assessment of possible concomitant diseases, since many of the relevant drugs may lead to adverse reactions and interfere with existing concurrent conditions.

2.2.5 Laboratory investigations

Typical findings are raised levels of the erythrocyte sedimentation rate (ESR) and/or CRP. Thrombocytosis and leucocytosis can be seen in active inflammatory disease. Reduced haemoglobin is also common. Serum iron may be lowered whereas ferritin concentration may be increased as a reflection of the acute phase reaction. It is important to do a general laboratory screening, including liver function tests and creatinine as well as urine examination to determine whether there are any indications of underlying liver or kidney abnormalities.

Tests for RF and ACPA are important both for the diagnosis and staging of the disease, since the presence of RF and ACPA are associated with a more severe disease course. The presence of RFs is generally determined by nephelometry for IgM RF or by ELISA for specific isotypes, including IgM RF, IgA RF or IgG RF. The anti-CCP2 ELISA, which uses different artificial CCPs, is the most common method for the detection of ACPA. Multiplex approaches for the simultaneous detection of ACPA directed against different citrullinated peptides are under investigation for routine practice, but for the moment these are limited to clinical research.

The levels of RF and ACPA have also been included in the recent ACR/EULAR 2010 classification criteria for RA (table 4). The detection of anti-CarP antibodies is not available in routine practice. The likelihood of radiographic progression after 5 years is significantly greater among patients with ACPA (OR = 2.5) (Meyer et al, 2003). Other immunological examinations may be important for differential diagnoses. It is common to test for the presence of antinuclear antibodies, but the value of this test can be questioned if there is no clinical evidence of any systemic connective tissue disease. The presence of antinuclear antibodies has not been shown to have any prognostic value in RA. However, secondary Sjögren's syndrome can be seen together with RA and infrequently, the typical immunological markers of Sjögren's syndrome (anti-SSA and anti-SSB) may also be present in RA.

2.2.6 Imaging procedures

Conventional radiographic examinations remain the 'gold standard' for diagnosing joint damage in RA. The majority of patients with newly diagnosed RA will not have any erosive changes and thus the absence of erosions on X-ray examination does not rule out a diagnosis of RA. Many patients will have completely normal X-ray findings initially or only soft tissue swelling and periarticular osteopenia. Radiographic examinations of the hands, wrists and feet are important as a baseline examination and for the subsequent monitoring of the disease.

Many clinicians perform only a posteroanterior (PA) view of the hands (with the wrists included) and a PA view of the feet (figure 13). The addition of three-quarter views (also known as the Nørgaard view or supinated-oblique view) may increase the probability of detecting erosions (Norgaard, 1965). In a pivotal paper published in 1977, it was shown that 71% of patients with early RA (defined by the authors as disease duration of <12 months) developed 'diagnostic' erosions in the first 5 years and of those developing erosions, 43% did so in the first year (Brook and Corbett, 1977). The MTP joints are commonly affected before involvement of the MCP joints and the 5th MTP joint particularly. Some patients demonstrate erosive changes of the MTP joints without involvement of the MCP joints. It is therefore recommended that hand and feet X-ray examinations are always performed together, even in patients without symptomatic involvement of the feet.

A baseline radiographic assessment is important in order to detect future radiographic progression, which is considered an unfavourable prognostic sign. Follow-up hand and feet radiographs are recommended annually in the early stages of the disease (Smolen et al, 2010*). Scoring systems have been developed and validated to assess the extent of, and changes in, radiographic damage, such as the modified Sharp–van der Heijde score, which is commonly used in clinical trials (van der Heijde, 2000).

Figure 13 Left: Plain X-ray picture of the metatarsophalangeal (MTP) joints of the right foot with erosions and joint space narrowing of the 4th and 5th MTP joints. Right: X-ray picture of the left hand with advanced carpal disease and involvement of the proximal interphalangeal and metacarpophalangeal joints.

Ultrasonography may be helpful in the identification of subclinical synovitis, both at disease onset to assist with diagnosis and throughout the course of the disease to evaluate disease activity. Grey-scale ultrasonography with Doppler imaging has been found to be more sensitive in detecting signs of inflammation and destruction in RA finger joints than clinical and radiographic examinations, without loss of specificity (Szkudlarek et al, 2006) (figure 14). The exact role and timing of ultrasonography is currently undergoing investigation.

Figure 14 Ultrasonography with Doppler of the metacarpophalangeal (MCP) joints. (A) Longitudinal view of the dorsal aspect of a MCP joint, with marked synovitis and presence of a strong Doppler signal. (B) Axial view of a metacarpal head with discontinuity of the cortical surface, representing an erosion. C, capsule; MC, metacarpal; PP, proximal phalanx; S, synovitis.

Ultrasonography can detect erosions of smaller joints at an early stage of the disease and often before the erosion is visible on conventional radiographs. This is particularly the case for the second and fifth MCP joints and the first and fifth MTP joints. A common presentation in early RA is extensor carpi ulnaris tenosynovitis of the wrist, which is easily demonstrated with joint ultrasound (see figure 15).

Figure 15 Wrist ultrasound with a longitudinal view of tenosynovitis demonstrating blurred tendon margins, an abnormal hypoechoic zone, representing fluid within the tenosynovial sheath and marked Doppler activity.

Magnetic resonance imaging (MRI) of the wrist and finger joints may be an important tool for early diagnosis and staging of the disease. The detection of synovitis is enhanced when the imaging procedure is performed with gadolinium contrast. Bone marrow oedema is also a typical finding, which is considered to be a predictor of subsequent erosions. Nevertheless, bone marrow oedema is a rather unspecific finding, which may also be seen in other joint diseases, such as osteoarthritis. Erosions are seen earlier with MRI than with conventional radiography. Routine use of MRI has not yet been introduced into clinical practice because of its high cost and lack of availability (Ostergaard et al, 2003a).

2.2.7 Diagnosis

RA is a clinical diagnosis based on the signs and symptoms that are considered typical of RA, by consideration of numerous contextual, personal, and geographic factors, and by excluding other diseases. Diagnosis cannot be established by using classification criteria, which are developed for clinical research purposes. However, the result of a classification may inform the ultimate clinical diagnosis. The 1987 ARA classification criteria (Arnett et al, 1988*) were found to be too insensitive in early arthritis, and the requirement of nodules or radiographic

damage in a 4/7 criteria system was considered not timely anymore (Aletaha et al, 2005). Subsequently, the 2010 ACR/EULAR classification criteria have been developed (Aletaha et al, 2010*), and it has been shown that these criteria show higher sensitivity at the cost of some specificity (Radner et al, 2014). Importantly, erosive disease that is typical for RA does not require the application of the classification system, but allows direct classification as RA. The erosiveness typical for RA has been defined (van der Heijde et al, 2013).

Table 4 2010 ACR/EULAR classification criteria for rheumatoid arthritis (RA). (Reproduced with permission from Aletaha et al, *Arthritis Rheum* 2010;62:2569–81)

Domain	Parameter	Points
A Joint involvement	1 large joint	0
	2-10 large joints	1
	1-3 small joints	2
	4-10 small joints	3
	>10 joints (≥ 1 small)	5
B Serology	Negative RF <i>and</i> negative ACPA	0
	Low positive RF <i>or</i> low positive ACPA	2
	High positive RF <i>or</i> high positive ACPA	3
C Acute-phase reactants	Normal CRP <i>and</i> normal ESR	0
	Abnormal CRP <i>or</i> abnormal ESR	1
D Symptom duration	<6 weeks	0
	≥ 6 weeks	1

RF or ACPA measurements between one and three times the upper limit of normal are designated 'low'; higher measurements are designated 'high'. CRP and ESR above the upper limit of normal are considered 'raised'. Scores for each of four domains are added; maximum score = 10. A score ≥ 6 indicates RA.

ACPA, anti-cyclic citrullinated peptide antibodies; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid arthritis.

2.2.8 Differential diagnoses

The differential diagnosis of RA is broad, especially given that RA does not always present in the classical polyarticular symmetric fashion. A comprehensive approach is necessary to differentiate RA from similar entities, which is a prerequisite to classify a patient according to the new ACR/EULAR classification criteria (Aletaha et al, 2010).

When arthritis is of acute onset, it is necessary to exclude infectious arthritis. While bacterial (septic) arthritis most commonly affects one joint and is associated with a severe clinical presentation with fever, leukocytosis and prostration, viral arthritis usually occurs in a polyarticular fashion similar to RA and may occasionally be associated with a rash. History taking is particularly important for an infection such as parvovirus B19, to explore potential contact with young children as a source of infection. Serological testing for parvovirus B19,

hepatitis B (HBV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), rubella and human immunodeficiency virus (HIV) should be performed in the setting of recent-onset oligo- or polyarthritis. It is useful for detecting an acute IgM antibody response in the first 3 months followed by the presence of IgG antibodies against the suspected agent. HCV-related arthritis may yield a high titer of RF (often with cryoglobulins), however, with an unremarkable level of ACPA. Arthritis associated with HCV, HIV, as well as Lyme and gonococcal arthritis may follow a more chronic pattern. Clues for gonococcal arthritis may be skin lesions such as pustules and blisters, as well as concurrent genital discharge. Lyme disease and gonorrhoea, however, infrequently cause arthritis in Europe.

Unlike the previously listed infectious arthritides, reactive arthritis is defined as a sterile oligo- to polyarthritis of acute or subacute onset, most commonly affecting the ankles and knees in an asymmetric fashion, but may resemble a symmetric polyarthritis of the hands as well. The typical presentation of reactive arthritis can be defined as a common syndrome that includes the co-presence of reactive arthritis, sterile conjunctivitis and urethritis. Reactive arthritis is induced by a variety of infectious agents, usually occurring 7 to 14 days following the (symptomatic or asymptomatic) infection of the urinary or gastrointestinal system caused by *Shigella*, *Salmonella*, *Campylobacter*, *E. coli*, *Yersinia*, *Chlamydia*, *Mycoplasma* or *Ureaplasma*. Rheumatic fever also causes reactive arthritis associated with *Streptococcus pyogenes*-related pharyngitis and commonly a positive anti-streptolysin titer, almost exclusively in younger patients. Reactive arthritis is RF negative and self-limited in most cases, although it can also persist and recur in a relapsing-remitting manner. A similar presentation can develop in the context of inflammatory bowel disease. Arthritis of acute or subacute onset with oligo- or less commonly polyarthritis similar to reactive arthritis may also develop in the context of adult-onset Still disease and Löfgren's syndrome as the acute-onset variant of sarcoidosis (acute arthritis, hilar lymphadenopathy and erythema nodosum).

Hand osteoarthritis is the most frequent differential diagnosis of chronic polyarthritis affecting the hands, especially in the elderly and middle-aged population. Several distinct features make the differentiation from RA relatively clear in the routine clinical setting: OA is characterized by non-inflammatory joint pain, normal levels of serum inflammatory markers and a non-inflammatory synovial fluid pattern (the analysis of which is rarely needed in the context of hand OA); furthermore, it has a predilection for DIPs and first CMC joints of the hands, sparing the radiocarpal and MCP joints. However, MCP joints may be affected by OA secondary to hemochromatosis. Differentiation between RA and OA may be less clear in the context of "inflammatory" OA when clinical signs of inflammatory polyarthritis, as well as erosive joint destruction develop.

Psoriatic arthritis is an important entity to discern both from RA and OA. It belongs to the spectrum of RF-negative (seronegative) arthritides and is not necessarily associated with psoriasis. A thorough screening for psoriasis should be performed (including the nails and less visible skin areas such as the navel, the scalp, the posterior auricle and the buttocks), as well as a detailed history of enthesitis, dactylitis and other extra-

articular signs of peripheral spondyloarthritides. The arthritis may be erosive as RA but has a greater predilection for DIPs and, despite resembling OA, is usually more destructive. Signs of bony proliferation on X-rays are typical for PsA and speak against RA.

Polymyalgia rheumatica (PMR) is the most important differential diagnosis of recent onset symmetric polyarthritis in the elderly population, given its similarity to seronegative late-onset RA (the so called “LORA”, late onset RA) and important prognostic implications if associated with giant cell vasculitis and not recognized. Despite the similarity, LORA does not typically present with myalgias and usually affects small joints of the hands unlike PMR that more commonly affects larger joints. Sudden onset polyarthritis in the elderly may also be associated with paraneoplastic syndromes, drug-induced lupus and remitting seronegative symmetric synovitis with pitting oedema (RS3PE).

Connective tissue diseases (CTDs, collagenoses) are another important, but less frequent, differential diagnosis, the onset of which is more common in younger and middle-aged patients. Systemic lupus erythematosus (SLE) may present with arthralgias and symmetrical polyarthritis, as well as Jaccoud’s arthropathy, a reversible mimic of RA with deformities. Although RA can be ANA positive as well as SLE and Sjögren’s syndrome, the latter two are associated with a variety of other typical organ-specific symptoms, as well as antibodies against specific antigens within the ANA spectrum. Despite SLE rarely being RF-positive, increased RF titers are a common finding in Sjögren’s syndrome. RF positive erosive arthritis in patients with SLE is considered to be an overlap syndrome of RA and SLE and is often termed “rhumus”. The “puffy” hands of systemic sclerosis, mixed connective tissue disease and polymyositis (in the context of anti-synthetase syndrome, often in conjunction with interstitial lung involvement) should also be considered in the differential diagnosis. The anti-synthetase syndrome is the most important differential diagnosis of RA with lung affection.

Crystal deposition disorders (gout and calcium pyrophosphate deposition disorder, CPPD) may cause various patterns of arthritis, most commonly oligo- or monoarthritis. A polyarticular pattern develops in approximately 10% of both and may resemble RA. Gout is more frequent in the context of metabolic syndrome, whereas CPPD is frequently seen in the elderly. A joint tap reveals intraarticular crystals. Ultrasound and dual-energy CT (in the case of gout) may help detect signs of crystal deposition. If not treated adequately, gout can transform to a chronic tophaceous disorder mimicking RA with rheumatoid nodules.

The incidence of various inflammatory arthropathies has been examined in Sweden (Soderlin et al, 2002) and in Finland (Savolainen et al, 2003) and these results highlight the fact that many different inflammatory arthropathies have to be considered in patients with recent-onset joint swelling (box 2).

2.2.9 Disease assessment

Several quantitative measures can be used to evaluate the activity and severity of the disease, as well as the disease consequences for the individual (table 5). The EULAR disease activity and response criteria are based on the Disease Activity Score, but several other scores mentioned below have been validated and are used in clinical practice. Core measures of disease activity include tender and swollen joint counts, patient and investigator global assessments of disease activity on a visual analogue scale (VAS), intensity of joint pain on a VAS, a patient-reported measure of physical disability (Health Assessment Questionnaire (HAQ)) and acute phase reactants (ESR and CRP).

Table 5 Three of the principal quantitative measures used to evaluate the activity and severity of RA and the predefined thresholds for remission, low, moderate and high disease activity

	DAS 28 (van Gestel et al, 1996)	SDAI (Smolen et al, 2003)	CDAI (Aletaha et al, 2005)
Scoring items:			
Number of variables	3 or 4	5	4
Tender joint count	✓	✓	✓
Swollen joint count	✓	✓	✓
CRP	✓ (CRP or ESR)	✓	
ESR			
Patient global assessment of disease activity	(✓)*	✓	✓
Physician global assessment of disease activity		✓	✓
Disease activity: (range)	0–9.3	0–86	0–76
Remission	≤2.6	≤3.3	≤2.8
Low	>2.6–≤3.2	>3.3–≤11	>2.8–≤10
Moderate	>3.2–≤5.1	>11–≤26	>10–≤22
High	>5.1	>26	>22

*This item is included in the DAS28 score with four variables.

CDAI, Clinical Disease Activity Index; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; DAS28, 28-joint count Disease Activity Score; SDAI, Simplified Disease Activity Index.

These individual disease activity measures can be combined into composite measures. The Disease Activity Score 28 (DAS28) includes the 28-swollen joint count (28-SJC) and the 28-tender joint count (28-TJC) in addition to patient global assessments of disease activity on a VAS, and ESR or CRP. The scores according to EULAR criteria are: ≤2.6 for remission, >2.6 and ≤3.2 for low disease activity, >3.2 and ≤5.1 for moderate disease activity and >5.1 for high disease activity (van Gestel et al, 1996). The Simplified Disease Activity Index (SDAI) (Smolen et al, 2003) is the numerical sum of five outcome parameters: tender and swollen joint counts (28-TJC and 28-SJC), patient and physician global assessments of disease activity (VAS 0–10 cm) and the level of CRP. The Clinical Disease Activity Index (Aletaha et al, 2005) is a simplification of the SDAI, without the laboratory evaluation of CRP to allow immediate clinical assessment. The DAS28 has repeatedly been reported to fail to provide criteria for remission with face validity, as it allows for multiple swollen joints in remission. Therefore, it has more recently been abandoned, and the 2011 ACR/EULAR remission criteria propose only SDAI as a score based criterion, in addition to the main Boolean definition (Felson et al, 2011).

Functional disability in RA is most commonly measured with the Stanford HAQ. The shortened version, the Modified HAQ, reduces the number of items from 20 to 8, one for each of the eight components and does not allow upgrading of scores by use of technical devices or help by another person. However, several other

generic and disease-specific measures are available for assessment of physical disability and other important dimensions of health-related quality of life (see online in-depth discussion I).

Joint damage is usually assessed by imaging modalities, using one of the accepted scoring systems to assess erosions and joint space narrowing. The most widely used radiological scoring systems are the Larsen score and the Sharp score (with modifications by Genant and van der Heijde). Clinical scores of deformities are also available (Zijlstra et al, 2002). Standardised scoring systems for synovitis and erosions on ultrasonography and MRI have also been published and validated for the hand and wrist joints with different qualitative (0/1) and semiquantitative (0–3) measuring systems (Ostergaard et al, 2003b; Mandl et al, 2011).

According to the most up-to-date ACR/EULAR definitions, RA can be considered to be in remission if either the SDAI is ≤ 3.3 , or if the scores for tender and swollen joint count, CRP (in mg/dL) and the patient's global assessment (0–10 scale) are all ≤ 1 (Felson et al, 2011*). Nevertheless, it is possible to be in remission according to these criteria and to still demonstrate ultrasound or MRI evidence of synovitis. Future definitions of remission may well incorporate these imaging modalities.

2.2.10 Identification of prognostic markers

Since RA can have a variable disease course, it is of particular importance and relevance to identify markers that may predict the disease outcome. In the ideal situation, one would be able to tailor treatment according to such indicators—that is, to treat patients with predictors of severe disease aggressively and to spare patients with mild disease from drugs that are associated with potentially severe adverse reactions.

Three different outcomes can be considered to be of particular relevance: radiographic damage, functional disability and mortality. Table 6 shows known predictors for these long-term outcomes. Radiographic progression is considered a key outcome variable, as it is thought to reflect the cumulative effect of inflammation on bone and cartilage. Further, joint damage accounts for a considerable amount of the disability in RA, in both the established and early phases of the disease (Odegard et al, 2006).

An optimal treatment strategy should include considerations of the presence or absence of predictors of joint damage, since prevention of such damage is a major treatment goal. Several studies have shown that female gender and the presence of erosions are predictors of progressive radiographic abnormalities in RA.

The prognostic markers that are most relevant to consider in clinical practice are one of the composite disease activity scores (such as the DAS28) and laboratory markers. Serum IgM RF and ACPA are strong predictors of radiographic damage, especially when present in high titres. Several studies have also shown that ESR and CRP are independent predictors of radiographic damage.

Table 6 Predictors of outcome in rheumatoid arthritis

Prediction of future physical disability (HAQ score)	Prediction of future structural damage	Prediction of increased mortality
<ul style="list-style-type: none"> ● HAQ score at 1 year ● Functional grade III or IV disease at 1 year ● Age > 65 ● Initial disease severity ● Comorbidities (diabetes, HT, CVD) ● Rheumatoid factor ● Baseline Larsen score ● DAS28 at 1 year ● Baseline haemoglobin ● Acute phase reactants (?) ● Gender (?) ● Level of education (?) 	<ul style="list-style-type: none"> ● ACPA ● Baseline erosive disease ● Female gender ● Acute phase reactants ● Rheumatoid factor ● TNF and IL-6 ● Genetic markers: HLA-DR4 and HLA-DRB1(shared epitope) ● HAQ score ● MRI activity 	<ul style="list-style-type: none"> ● Age ● Level of education/coping ● Physical status ● Rheumatoid factor ● Comorbidities ● Infections ● Extra-articular manifestations ● Increasing HAQ scores ● Baseline poor health status ● Use of glucocorticoids ● Gender (?) ● Acute phase reactants (?) ● Structural damage (?)

ACPA, anti-cyclic citrullinated peptide antibodies; CVD, cardiovascular disease; DAS28, 28-joint count Disease Activity Score; HAQ, Health Assessment Questionnaire; HT, hypertension; IL, interleukin; TNF, tumour necrosis factor.

One Norwegian study showed that ACPA, IgM RF, ESR and female gender were all independent predictors of radiographic progression and could be combined into an algorithm for better prediction of disease outcome. ACPA was the strongest contributor to the overall prediction model. In this study, patients with high levels of ACPA were 10 times more likely than ACPA-negative patients to develop radiographic progression and about five times more likely than patients with low–moderate levels (Syversen et al, 2008). The algorithm with ACPA, IgM RF, high ESR and female gender predicted radiographic progression at the individual level with good accuracy (figure 16). Prediction of mild disease (specificity), however, is more difficult than prediction of progressive disease (sensitivity).

In summary, an appropriate investigation in early RA should include the evaluation of both diagnostic and prognostic markers by assessing signs of structural damage, acute phase reactants, number of swollen joints, rheumatoid factor, ACPA and disability level. Patients with markers indicating potentially severe and progressive disease should have the highest priority for early and aggressive treatment.

Figure 16 Probability of radiographic progression – blue bars: male subjects, red bars: female subjects. CCP, cyclic citrullinated peptide; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor. (Reproduced from Syversen et al, *Ann Rheum Dis* 2008;67:212–7.)

2.3 Recent-onset arthritis

In new-onset polyarthritis, while awaiting confirmation of the diagnosis or when the diagnostic investigations do not establish a precise diagnosis, the term ‘undifferentiated arthritis’ (UA) or undifferentiated inflammatory arthritis is often employed. UA is a diagnosis of exclusion, defined as an *early* form of arthritis not meeting classification/diagnostic criteria for a more definitive disease (McNally et al, 2014). *Nota bene*, there is no consensus on the temporal definition of “early arthritis”, although a time span of 3-6 months of symptom onset is usually understood under this term.

The definition of UA depends on the current armamentarium of criteria used to describe and classify various diseases that should be considered in the differential diagnosis of recent-onset arthritis. Until the 2010 ACR/EULAR criteria for the classification of RA were published (Aletaha et al, 2010), the 1987 ARA criteria (Arnett et al, 1988) were used as the classification standard and most of our current knowledge about the progression from UA to RA is still based on the fulfilment of the 1987 criteria as the outcome. Up to one-half of UA patients experience spontaneous remission, whereas one-third develop RA, i.e. meet the 1987 criteria (van der Helm-van Mil et al, 2007). Based on data from the Leiden Early Arthritis Clinic, nine features were identified as predictors of one-year progression from UA to RA in a prediction rule validated on several cohorts (van der Helm-van Mil et al, 2007; McNally et al, 2014): age, female gender, distribution of affected joints (favouring small joints, symmetric involvement, involvement of both upper and lower extremities), tender and

swollen joint counts (TJCs and SJs), duration of morning stiffness, level of CRP, as well as RF and anti-CCP positivity (van der Helm-van Mil et al, 2007). A similar prediction rule was constructed using exclusively MRI findings and serologic variables (Tamai et al, 2009). It is noteworthy that not only ACPA positivity, but also the titer of anti-CCP2 antibodies as the standard of ACPA detection, serves as a predictor of transformation of UA to RA – the time span between symptom onset and fulfilment of the 1987 criteria is shorter in patients displaying high anti-CCP2 titers at baseline (Bizzaro et al, 2013). This is in line with the approach used in the 2010 criteria ascribing a higher score to high-titer compared to low-titer antibody levels (Aletaha et al, 2010). On the other hand, the already mentioned role of RF positivity in predicting evolution of UA to RA (Rantapää-Dahlqvist et al, 2003; van der Helm-van Mil et al, 2007) is not unequivocally accepted (Bizzaro et al, 2013; Chen et al, 2013), possibly due to their lower specificity. Furthermore, although a likelihood of persistent arthritis increasing with the titer of RF has been demonstrated (Mjaavatten et al, 2010), this role of RF is not unequivocally confirmed to be independent of the ACPA status (Bizzaro et al, 2013).

With the emergence of the more sensitive 2010 ACR/EULAR criteria, a proportion of patients previously considered UA became classified as RA (Jung et al, 2012). The new criteria contain most of the clinically relevant features included in the Leiden prediction rule and their employment successfully discriminates patients with a high from those with a low risk of radiographic progression (Mueller et al, 2015). In the IMPROVED study, patients with UA not fulfilling the 2010 criteria have been shown to be less active (according to DAS) with lower TJCs and SJs, a much lower percentage of ACPA and RF positivity compared to RA (ACPA: 3% vs 68%; RF: 4% vs 69%), as well as a more favourable outcome in terms of radiographic progression (Heimans et al, 2015). However, the fact that 23% of UA patients from the Leiden Early Arthritis Clinic not fulfilling the 2010 criteria still fulfilled the 1987 criteria within one year of symptom onset indicates the need of careful monitoring of UA patients, at least over the first years of the disease course (Krabben et al, 2012).

Nevertheless, given that the 2010 classification criteria exclude only those UA patients identified to have a low risk of RA development according to the previously mentioned prediction rule (van der Helm-van Mil, 2007), it is reasonable to initiate therapy when a given patient fits in the new classification (Smolen et al, 2014). Otherwise, treatment with a DMARD should be considered as early as possible in patients with UA under risk of persistent or erosive arthritis and in patients already having joint erosions (Combe B et al, 2007).

Tight control of disease activity in the early period following symptom onset is critical to induce remission or to achieve a low disease activity and to prevent future damage and disability, because of the close relationship between level of inflammatory activity and future damage. It is therefore recommended that patients should be followed up and disease activity assessed by the DAS28 and by a patient-reported outcome such as the HAQ.

The 'treat-to-target' approach represents a treatment strategy tailored to the disease activity of the individual patient with RA with the aim of achieving a predefined level of low disease activity or remission. The patient's disease is reviewed regularly (1–3 monthly during active disease) and treatment is adjusted until the target is achieved. An international taskforce of RA experts developed 10 recommendations to inform patients and practitioners about strategies to reach optimal outcomes and concluded that treat to target is an important concept in the induction of remission in the treatment of RA (Smolen et al, 2016*).

In the Dutch 'DREAM' RA registry, treating to the target of remission (DAS28 < 2.6) in early RA has been found to be cost-effective as compared with 'usual care' and to lead to high rates of sustained remission (62% of patients in DAS remission after 3 years) (Vermeer et al, 2013a; Vermeer et al, 2013b). This concept of treat to target is supported by other studies, such as the TICORA study (Grigor et al, 2004*), in which patients who were followed up with tight control of disease activity had less radiographic progression than patients followed up by a standard regimen.

2.4 Established disease

The clinical challenge in patients with established disease is different from that of recent-onset or early RA. The joint involvement can be dominated by deformities as a consequence of longstanding inflammation and radiographic damage. However, active inflammation may still be present and should be treated, in order to prevent further radiographic damage, deformities and disability. Imaging modalities such as ultrasound and MRI may be useful to assist the practitioner in distinguishing between mechanical and inflammatory joint pain.

In established RA, it is also particularly important to be aware of the extra-articular manifestations and the possibility of involvement of internal organs. Surgical procedures with joint replacement may be required for certain patients and a detailed examination of joints, with particular focus on the functional consequences of the deformities, may be clinically relevant.

2.4.1 Involvement of hands

The MCP and PIP joints are frequently involved in RA. Involvement of the DIP joint is uncommon and is more likely to indicate concurrent osteoarthritis, psoriatic arthritis or gout. Deformities of the PIP joints usually result from lack of ligament support. Boutonnière deformity (figure 17) describes a finger with flexion of the PIP joint and hyperextension of the DIP joint, due to relaxation and volar displacement of the central tendon slip at the PIP joint. A similar deformity of the thumb is known as a 'Z-shaped' deformity due to flexion of the MCP joint and hyperextension of the IP joint at 90 degrees (figure 18). A swan-neck deformity of the finger describes hyperextension of the PIP joint and flexion of the DIP joint (figure 19). Deformities of the MCP joints include volar subluxation, which may be seen as a step-like, ulnar drift (often in combination with radial deviation of the wrist) and flexion deformities.

Figure 17 Boutonnière deformity of the ring finger. (Source: Cofer, <http://www.lecofer.org>.)

Figure 18 Z-shaped deformity of the thumb.

Figure 19 Swan-neck deformity of the 5th digit.

Wrist deformities include volar subluxation with a visible step opposite the radiocarpal joint, and radial deviation of the carpus from the axis of the wrist and hand. Arthritis of the distal radio-ulnar joint results in instability and dorsal subluxation of the ulnar head with a 'piano key' movement on downward pressure. Dorsal subluxation of the ulnar head with erosive abnormalities will often lead to rupture of the neighbouring extensor tendons (figure 20).

Figure 20 Rupture of the extensor tendons. (Source: Cofer, <http://www.lecofer.org>.)

2.4.2 Elbow and shoulder

The elbow joint is frequently involved in established RA and much less commonly in OA, unless there is a history of local trauma. Loss of extension with a fixed flexion deformity is a typical early sign. Functionally, loss of supination is disabling when eating and performing daily activities. The other disabling limited motion is reduced flexion. This may lead to an inability to perform personal grooming of the hair and face. Thus, the maintenance of flexion and supination is an extremely important functional objective.

Shoulder involvement in RA is less common, but in most patients with severe disabling RA the shoulder will be affected to some degree. Shoulder symptoms usually appear when joint destruction has become advanced and this tends to limit daily self-care activities. Synovitis leads to erosion and damage of both the humeral head and the glenoid fossa. The long head of the biceps tendon may rupture. The rotator cuff is also frequently involved, with inflammation, tendon rupture and bursitis. Involvement of the acromio-clavicular joint is uncommon.

2.4.3 Cervical spine

Involvement of the cervical spine is relatively rare but potentially life-threatening. There is a synovial articulation between the transverse ligaments of the atlas of the posterior aspect of the odontoid (dens). This thick strong transverse ligament acts as a sling in maintaining the odontoid process against the posterior surface of the atlas and thus prevents forward movement of C1 on C2. Persistent synovitis of this joint may produce erosions of the dens, compromising the transverse ligament and resulting in instability. The space between the anterior aspect odontoid process (C2) and the posterior surface of the anterior arch of the atlas (C1) normally measures ≤ 3 mm. If this space exceeds 5 mm (some clinicians will say 3 mm) the condition is defined as atlantoaxial (or C1–C2) subluxation. Synovial involvement may also affect the apophyseal joints in the cervical spine. The consequence of synovitis in this area may be an atlantoaxial subluxation with neurological symptoms due to cervical myelopathy.

When considering the cervical spine at the C1–C2 level it is helpful to divide the space through the arch of the atlas into thirds, one-third for the odontoid process, one-third for the spinal cord and one-third free (figure 21). If the C1–C2 subluxation exceeds 10 mm, the free third is lost and cervical cord damage becomes a significant risk owing to direct contact between the odontoid process and the spinal cord.

In severe cases, vertical dislocations may also occur with the odontoid process penetrating upwards into the foramen magnum, compressing the brainstem (basilar invagination), which may be fatal. Thankfully, this is now an exceedingly rare occurrence.

When a patient with RA requires surgery, the presence of cervical subluxation presents a significant risk during general anaesthesia, due to intubation with the neck in an extended position. Consequently, routine lateral cervical radiographs with the head in a neutral and a flexed position are recommended before surgical procedures. An open-mouth frontal X-ray examination demonstrating the odontoid may also be useful. Special precautions are required preoperatively to prevent cervical cord damage when atlantoaxial subluxation is detected.

Figure 21 Schematic axial representation of the atlantoaxial joint from above. (A) In a healthy state; (B) after rupture of the transverse ligament with anterior translation of the atlas ring.

The use of other imaging modalities such as MRI to determine the degree of active synovitis and pannus formation (figure 22) and CT to better visualise the presence of erosive disease (figure 23), is becoming increasingly frequent. Nevertheless, these techniques are ‘static’ and do not replace the need for ‘dynamic’ radiographs.

Figure 22 MRI of the cervical spine with sagittal T1 FLAIR (left) and sagittal T2-weighted images (right). Pannus formation (long arrow) with low signal intensity on T1- and T2-weighted sequences behind the odontoid process with compression of the spinal cord at the level of C1. (Reproduced with permission from Del Grande et al, *Semin Arthritis Rheum* 2014;43:738–44.)

Figure 23 CT scan of the cervical spine with coronal (left) and sagittal (right) images, with presence of erosions of the odontoid process (arrow). (Reproduced with permission from Del Grande et al, Semin Arthritis Rheum 2014;43:738–44.)

Wearing a stiff cervical collar can be an important treatment for patients with atlantoaxial subluxation, especially when there is risk of neck injury. Some patients with significant cervical instability and/or neurological impairment will require surgical procedures with fixation to stabilise the cervical spine.

2.4.4 Joints of the lower limbs

The hip is infrequently involved in RA, but may be affected either directly by the disease or indirectly via secondary OA. Knee involvement, however, is much more common in RA. Synovial effusion is the typical sign of inflammatory activity of the knee. Patients with knee swelling have a tendency to assume a more comfortable position with the knee flexed and if this becomes a habit, a loss of full knee extension eventually results.

Posterior knee pain may be due to a cyst in the popliteal region, called a Baker's cyst. This cyst can extend from its location in the gastrocnemius bursa down into the medial aspects of the calf. This is best seen when the patient is standing. The Baker's cyst arises as an extension from the joint cavity. Rupture of this cyst can result in generalised swelling of the calf and a clinical picture which mimics deep vein thrombosis. Destruction of the knee joint may lead to instability due to laxity of the collateral and cruciate ligaments. This laxity is detected by stressing the knee joint for lateral and medial collateral stability. A particular problem arises in women with physiological valgus. This valgus increases the load on the lateral compartment and as the valgus increases due to arthritis, the loading will also increase so that a vicious cycle occurs. Varus deformity is more common in OA than in RA.

Within the foot, the subtalar and mid-tarsal joints are more frequently involved than the talocrural joint (figure 24). The ankle is usually quite stable, but reduced dorsal flexion may interfere with walking, particularly on an incline. The subtalar and talonavicular joints are commonly affected in RA. Synovitis causes pain and stiffness and may occasionally lead to subtalar dislocation. As cartilage loss progresses and bone erosions develop, valgus deformity increases with progressive flattening of the longitudinal arch. Involvement of the MTP joints is common in RA, causing pain and disability. Forefoot deformity starts with synovitis of the MTP joints and involvement of the flexor tendons, which can result in clawing of the toes and dorsal dislocation of the MTP joints (figure 25). The metatarsal heads can be destroyed owing to the synovitis and this can lead to extreme pain. The forefoot in longstanding RA takes on a triangular appearance (figure 26).

Figure 24 Ankle involvement in early RA.

Figure 25 Rheumatoid foot with clawing of multiple toes.

Figure 26 Characteristic deformity of the feet in rheumatoid arthritis with lateral deviation at the metatarsophalangeal joints and a triangular shape with *halux valgus* and *quintus varus*.

2.4.5 Other joint areas

The temporal mandibular joint may be involved with tenderness and painful limitation of mouth opening. Occasionally the cricoarytenoid joint may be involved and associated with voice hoarseness. The ossicles of the ear may rarely be involved with hearing loss independent of medication-induced effects.

2.4.6 Nodules, tenosynovitis and bursitis

Rheumatoid nodules are the most frequent inflammatory extra-articular feature of RA, affecting approximately 40% of South European and up to 65% of patients from Anglo Saxon countries (Carmona et al, 2003). Histologically, they are Th1 granulomas containing three main cell types: activated macrophages, T lymphocytes and dendritic cells. The cytokine pattern within the nodule is similar to that in the synovial lesion (Hessian et al, 2003). Nodules may form over pressure locations such as the dorsal elbow, occiput, palms of the hands and Achilles tendon (figure 27). Gouty tophi may have a similar appearance and distribution, although they tend to be in close proximity to the joint or in a bursa.

Rheumatoid nodules are almost exclusively seen in seropositive disease, they occur more commonly later in the disease course, and are associated with other extra-articular features of RA (Turesson et al, 2008). Despite the fact that early occurrence of rheumatoid nodules was univariately associated with greater radiographic progression within five years, this association did not turn out to be independent of baseline damage and ACPA positivity (Nyhall-Wahlin BM et al, 2011). Similarly, rheumatoid nodules have been associated with the occurrence of cardiovascular events when adjusted for traditional cardiovascular risk factors, but not independently of RA-specific variables (Kaushik et al, 2015). Thus, rheumatoid nodules may be perceived as a useful clinical indicator of worse prognosis, but in the context of other relevant disease features.

Figure 27 Rheumatoid nodules in rheumatoid arthritis. (Source: Cofer, <http://www.lecofer.org>.)

Flexor tenosynovitis can lead to loss of active flexion. A trigger finger is a frequent feature of flexor tenosynovitis. The pathology is a thickening of the tendon with stenosis within the tendon sheath. A rupture of flexor tendons may occur but these are much less common than extensor tendon ruptures.

Flexor tenosynovitis at the level of the carpal tunnel may lead to entrapment of the median nerve and development of a carpal tunnel syndrome. The patients will have weakness and finger tingling and sensory loss, especially in the index and middle finger. Diagnosis can be established by nerve conduction studies or by ultrasonography. Extensor tendon involvement often manifests as a swelling of the dorsum of the wrist, below the extensor retinaculum. Asking the patients to extend the fingers will accentuate the swelling. One of the most common sites of tenosynovitis in active RA is the extensor carpi ulnaris on the ulnar aspect of the wrist joint.

Bursae should not be overlooked in the evaluation of any joint region. The bursae are lined by a synovial membrane that secretes synovial fluid and may develop rheumatoid synovitis. Involvement of the olecranon bursa by RA is a typical example of bursitis. Other bursae that are frequently involved are the subacromial bursa (in the shoulder), the trochanteric bursa (at the greater trochanter) and the retro-calcaneal bursa (adjacent to the Achilles tendon).

2.4.7 Extra-articular manifestations and RA-related comorbidities

Extra-articular manifestations and RA-related comorbidities are listed in table 7.

2.4.7.1 Secondary osteoporosis

RA is associated with an increased generalised bone loss, as diagnosed by a reduced bone mineral density (Haugeberg et al, 2000). Increased occurrence of vertebral and non-vertebral fractures has also been demonstrated. It has also been shown that RA is independently associated with increased occurrence of vertebral fractures (Orstavik et al, 2004). There is a twofold increase in the occurrence of osteoporosis both in men and women with RA. It is generally assumed that osteoporosis is due to inflammation (eg, cytokine release with osteoclast activation), but the use of glucocorticoids and immobility are also significant risk factors. It is important to assess bone mineral density in patients at risk. Preventive treatment (with vitamin D and calcium) should be considered, with the addition of anti-resorptive therapy when indicated.

Table 7 Extra-articular manifestations of rheumatoid arthritis

Haematological	Anaemia Thrombocytosis Leucopenia and thrombopenia (with Felty's syndrome)
Pulmonary	Diffuse interstitial fibrosis Pleural effusion Nodules Fibrosing alveolitis Bronchial dilatation Pneumoconiosis (Caplan's syndrome) Pulmonary hypertension (rare) Obliterative bronchiolitis (extremely rare)
Hepatic	Liver function abnormalities
Ocular	Keratoconjunctivitis sicca Episcleritis or scleritis
Vasculitis	Nail fold Systemic
Cardiac	Pericarditis Pericardial effusion Valvular heart disease Conduction defects
Neurological	Nerve entrapment Cervical myelopathy (atlantoaxial subluxation) Neuropathy: peripheral neuropathy or mononeuritis multiplex
Cutaneous	Subcutaneous nodules Pyoderma gangrenosum Vasculitic rashes Leg ulceration Amyloidosis

2.4.7.2 Muscles

Muscle weakness and atrophy (figure 28) are common in RA and may be secondary to neuropathy, glucocorticoid use, or immobility due to joint pain and swelling.

Figure 28 Interosseous muscle atrophy. (Source: Cofer, <http://www.lecofer.org>.)

2.4.7.3 Secondary Sjögren's syndrome

Secondary Sjögren's syndrome is a relatively frequent manifestation of RA with 'sicca symptoms', signifying dry eyes and dryness of the mouth. The exocrine function of tear glands and salivary glands may be altered in rheumatological disorders such as Sjögren's syndrome, or secondary to RA and other connective tissue disorders. Some studies have shown that RA with secondary Sjögren's syndrome may present with mild clinical manifestations or may even be asymptomatic, although there are usually clear histological changes in the salivary glands. Sicca symptoms are common in RA and about 10% of patients have secondary Sjögren's syndrome. The diagnosis can be established by testing for reduced saliva and tear production. Tear production can be assessed with the Schirmer test and it is performed by placing a test strip inside the lower eyelid. Local anaesthetic drops can be placed into the eye before the test to prevent tearing due to irritation from the test strip. After 5 min the strips are examined and a positive result is recorded if the strips show moistening of ≤ 5 mm in one or both eyes.

2.4.7.4 Other eye complications

Scleritis, episcleritis or both can occur in patients with RA, but are rather infrequent. Episcleritis may have an extremely rapid onset with the eye becoming red within minutes. Unlike other inflammatory conditions of the eye, episcleritis results in no discharge other than tearing. Loss of vision does not occur as a direct result of episcleritis but cataracts may develop secondarily and cause visual loss. Scleritis causes severe ocular pain and a dark red discolouration and can lead to vision-threatening perforation.

2.4.7.5 Infections

The incidence of bacterial infections is increased in patients with RA, partly owing to the disease itself and partly owing to the use of immunosuppressive drugs, such as glucocorticoids, disease-modifying drugs (DMARDs) and various biological agents. Registry data suggest approximately a doubling of the risk of a serious infection with anti-TNF therapy (van Dartel et al, 2013). The most common sites of infection are the respiratory tract and the skin. The risk of septic arthritis is also increased in patients with RA and it can be extremely challenging to differentiate between an acute flare of monoarthritis secondary to RA and a septic arthritis. It is therefore critical to urgently aspirate the joint and to organise a Gram stain and culture of the synovial fluid.

2.4.7.6 Cancer

There is a slightly increased risk of malignancy in patients with RA, especially lymphoma in certain patient subsets, such as those with longstanding disease and seropositive patients. It has been clearly shown that this risk is related to the severity and inflammatory activity of the disease (Baecklund et al, 2006). The anti-TNF agents do not appear to increase the overall rate of malignancy, except for skin cancers (melanoma and non-melanoma), where the risk is about doubled (Raaschou et al, 2013). Consequently, regular clinical examination for lymph nodes and dermatological review are important.

2.4.7.7 Haematological abnormalities

The majority of patients with RA have a mild normocytic hypochromic anaemia that correlates with elevation of the acute phase reactants and the activity of the disease. A few of these patients respond to treatment with iron. Folate and B12 deficiency may also be a cause of anaemia in RA. Thrombocytosis is frequent in RA and is related to disease activity. Leucopenia (particularly neutropenia) and thrombopenia in association with splenomegaly suggest Felty's syndrome.

2.4.7.8 Vasculitis

One of the initial pathological changes in RA includes inflammatory changes in small blood vessels. However, when considering vasculitis as a complication, the focus is more on the arteries or arterioles. Typical

manifestations include purpuric lesions on the skin that can subsequently develop into cutaneous ulceration (figure 29), peripheral neuropathy or involvement of internal organs. Vasculitis is fortunately rather uncommon. The presence of vasculitis is associated with disease severity, although it does not necessarily parallel the activity of the joint manifestations. A form of localised RA vasculitis with small periungual lesions is generally benign and does not require additional immunosuppressive therapy.

Figure 29 Cutaneous vasculitis. (Source: Cofer, <http://www.lecofer.org>.)

The two common neurological manifestations are a mild distal sensory neuropathy and a severe sensory motor neuropathy (mononeuritis multiplex). The latter form is characterised by severe arterial damage on nerve biopsy specimens. Symptoms of the milder form include paraesthesias or burning in a stocking and glove distribution, in association with decreased touch and pin-prick sensation. Organ-specific vasculitis can lead to organ infarctions. Neurovascular disease may be the only manifestation of vasculitis and establishing the diagnosis is often challenging. Severe organ-threatening vasculitis must be managed aggressively with high-dose glucocorticoids and immunosuppressive agents.

2.4.7.9 Renal disease

The kidney is rarely affected directly in RA but membranous nephropathy, vasculitis and secondary amyloidosis have been described. However, both analgesics such as the non-steroidal anti-inflammatory drugs (NSAIDs) as well as some DMARDs (eg, gold, ciclosporin) can affect renal function, resulting in raised serum creatinine and/or proteinuria.

2.4.7.10 Pulmonary disease

RA-associated lung disease has become recognized as a relatively frequent extra-articular disease manifestation, with a prevalence within the range between 5% and 30% (Chansakul et al, 2015; Cavagna et al, 2013), reaching even 67% (Bilgici et al, 2005). The rather wide range of estimated prevalence is a result of differences in study designs and studied populations, as well as lacking diagnostic and classification criteria for lung affection in patients with RA. Nevertheless, it is widely accepted that lung disease in RA patients may be caused by the disease itself, by infections or by drugs used to treat the disease.

The disease itself may affect the pleura, the lung parenchyma, large and small airways, as well as – less commonly – the pulmonary vasculature (Chansakul et al, 2015). All of these presentations may be asymptomatic and occasionally precede the articular features of RA (Lee et al, 2005). Pleural disease in RA presents as pleuritis with or without secondary pleural exudative effusion and fibrosis, and – less frequently – as bronchopleural fistula and pneumothorax due to ruptured subpleural rheumatoid nodules (Chansakul et al, 2015).

Parenchymal affection comprises interstitial lung disease (RA-ILD) and the relatively uncommon pulmonary rheumatoid nodulosis. Interstitial lung disease (ILD) is rather common in longstanding RA, with an estimated prevalence of up to 67% (Bilgici et al, 2005). However, ILD-related HRCT features were identified in almost 30% of RA patients within two years from disease onset (Habib et al, 2011). RA-ILD is more common in men, aged over 60 years, in smokers and in those with high titres of RF (Cavagna et al, 2013). The description of RA-ILD follows the American Thoracic Society/European Respiratory Society international consensus classification of idiopathic interstitial pneumonias (American Thoracic Society and European Respiratory Society, 2002) and its recent update (Travis et al, 2013), given the lack of a dedicated classification. About 50% of patients with RA with ILD have the usual interstitial pneumonia (UIP) subtype with bilateral subpleural predominantly basal reticulation, with honeycombing on HRCT, about a third, the non-specific interstitial pneumonia (NSIP) subtype with predominant ground-glass abnormalities, followed by organising pneumonia (OP) with patchy areas of consolidation. Organising pneumonia, in particular, responds well to glucocorticoid treatment, while the patients with usual interstitial pneumonia usually far worse. Less common patterns observed in the context of RA-ILD are desquamative interstitial pneumonia (DIP), lymphocytic interstitial pneumonia (LIP), acute interstitial pneumonia (AIP) and diffuse alveolar damage (DAD) (Yunt and Solomon, 2015). HRCT is the initial method of choice to determine the ILD subset, especially for UIP and NSIP where its accuracy compared to histological diagnosis has been reported to be about 70% (Cavagna et al, 2013). Biopsy should still be performed in cases of less typical HRCT findings to exclude infection and to discern between UIP and other RA-ILD subtypes in patients not responding to treatment (Lee et al, 2005).

Nodular lung disease is an uncommon feature, more frequent in patients with subcutaneous rheumatoid nodules and in patients with a high RF titer (Capobianco et al, 2012)(figure 30). Pulmonary rheumatoid nodules are usually asymptomatic and the prognosis is generally good, although complications may occur. They may pose a diagnostic challenge, especially when presenting as a single nodule, which may mimic malignancy or infection. Calcified pulmonary nodules are a feature typical for Caplan's syndrome – pulmonary nodulosis in patients with pneumoconiosis.

Both the large and small airways may be affected in RA. Lung function tests and HRCT are essential to determine the nature and extent of airway involvement. Bronchiectasis is the most common disease of the airways in RA, affecting up to 50% of patients (Junt and Solomon, 2015). Their significance lies in the increased risk of infections.

Patients with RA are prone to respiratory infections owing to their use of immunosuppressive medication. Pneumonia due to opportunistic infection can mimic ILD, which can be challenging, especially in the context of previously known ILD (Cavagna et al, 2013).

Last but not least, the possibility of drug-related lung disease must always be taken into account in any patients with RA who present with new-onset cough or shortness of breath (Amital et al, 2011). Drugs associated with the occurrence of lung disease are methotrexate, TNF-alpha inhibitors, leflunomide, rituximab, sulfasalazine and tocilizumab (Yunt and Salomon, 2015). New-onset pulmonary disease including various ILD subtypes have been described in the context of their use. However, the mechanism and causality of these relationships still remains to be clarified (Shaw et al, 2015).

Figure 30 Pulmonary disease in rheumatoid arthritis. Upper left: excavated pulmonary nodule; upper centre: calcified pleural nodule; upper right: bronchiectasis; lower left: usual interstitial pneumonia (UIP); lower centre: honeycombing; lower right: coronal image of UIP.

2.4.7.11 Cardiac complications

Pericarditis can be seen as part of the inflammatory activity with RA and is often present concurrently with pleuritis. Inflammation of the myocardium and endocardial inflammation may also be present. These manifestations generally resolve as disease activity is controlled. Conduction defects and haemodynamically significant valvular lesions are uncommon.

2.4.7.12 Arteriosclerosis

Several studies have shown that patients with RA have an increased risk of clinical coronary heart disease (CHD) compared with age- and sex-matched subjects without RA and that this risk is maintained after controlling for traditional CHD risk factors (diabetes mellitus, hypertension, dyslipidaemia, body mass index and smoking). One study suggested that the risk of CHD in patients with RA even precedes the ACR criteria-based diagnosis of RA (Maradit-Kremers et al, 2005).

Some studies support the view that atherosclerosis correlates with the level of systemic inflammatory activity over time and that the inflammatory process affects cardiovascular morbidity and mortality and accelerated coronary and extra coronary atherosclerosis (Chung et al, 2007). The therapeutic consequence is that anti-

inflammatory therapy may reduce the cardiovascular risk and some studies have supported this by showing that treatment with methotrexate (Choi et al, 2002) and anti-TNF agents (Jacobsson et al, 2005) may reduce cardiovascular morbidity and mortality. Several biological agents such as tocilizumab (anti-IL-6R monoclonal antibody) and tofacitinib (anti-JAK) tend to increase serum levels of low-density lipoprotein cholesterol. However, the clinical relevance of these changes to cardiovascular outcomes is unknown.

2.4.7.13 Gastrointestinal manifestations

RA does not affect the gastrointestinal tract directly. Gastro-duodenal ulcers are, however, rather frequent owing to the use of NSAIDs, which is why proton-pump inhibitors are routinely prescribed to patients with RA receiving chronic NSAID therapy. Liver disease may also be secondary to drugs commonly used in RA, such as methotrexate, NSAIDs and paracetamol. Liver involvement may be present in up to two-thirds of patients with Felty's syndrome. Liver biopsies are now rarely required, although abdominal ultrasound and fibro-scans may be of some use in monitoring patients with liver function test abnormalities.

2.4.7.14 Secondary amyloidosis

Secondary amyloidosis is an increasingly uncommon complication of RA. This is thought to be related to the implementation of more effective treatment strategies in RA. Amyloidosis results from the deposition in various organs (such as the kidneys) of an autologous protein in an insoluble fibrillar form. In patients with RA, excess serum amyloid A protein production is stimulated by the cytokines of the inflammatory response. Previously, renal amyloidosis was a rather frequent complication, leading to renal failure, dialysis and renal transplantation, but this should now primarily be regarded as treatment failure of RA itself.

Although the diagnosis of amyloidosis may be suspected on the basis of history and clinical manifestations, a tissue biopsy should be used to confirm the diagnosis. An abdominal fat pad biopsy is recommended for patients with more than one organ affected. In patients with just one organ involved, biopsy of the clinically affected organ is suggested as fat pad biopsy has a low sensitivity for amyloidosis in these patients.

2.4.8 Functional disability and its consequences

RA is associated with significant pain and joint destruction, as well as progressive loss of mobility and the ability to care for oneself (figure 31). Pain is the area of health in which most patients would like to see improvement (Heiberg and Kvien, 2002). Important correlates of functional disability in patients with RA include female sex, age, disease duration and disease activity measures, such as the Ritchie articular index and ESR, which can be considered predictors of a poorer functional status.

Figure 31 X-ray picture of a right hand in longstanding erosive rheumatoid arthritis with arthrodesis of the wrist, Z-shaped deformity of the thumb and subluxation of the metacarpophalangeal joints, resulting in significant functional impairment.

In addition to indicating a requirement for more aggressive treatment, high levels of disability have a negative impact on the psychological and social functioning of a patient, the consequences of which include mental distress, depression and fatigue. Pain and disability are the two variables most consistently related to mental distress, and high levels of disability with a consequently decreased ability to cope are commonly associated with depression, even in the early stages of the illness. This association of RA with depression has important implications for the overall healthcare burden of the disease and points to the need to deal with depression as part of a patient's comprehensive treatment plan.

Fatigue is also a significant and frequently debilitating problem for people with RA, as it contributes to work difficulties, reduced ability to participate in rehabilitation programmes and strained personal relationships. The FACIT (Functional Assessment of Chronic Illness Therapy) measurement system is a collection of health-related quality-of-life questionnaires that can be used to measure fatigue. Fatigue scores are significantly higher in patients with RA than in healthy individuals, and patients with RA with a history of affective disorder have higher levels of fatigue than those without such a history. The fatigue experienced by the patients with RA is strongly associated with disease severity measured by DAS28 and Clinical Disease Activity Index scores and is independent of anaemia.

2.4.9 Mortality

While RA has traditionally been regarded as a chronic, painful, disabling condition with an essentially non-fatal outcome, numerous studies conducted over the past four decades have found that it is associated with an increased mortality in comparison with the general population of the same age and gender. Standardised mortality ratios (ie, the ratio of deaths among patients with RA compared with the age-matched general population) have been reported to range from 1.16 to 3.0 in studies conducted in various countries. Some studies show a more pronounced increase in mortality in women. Disease severity, activity and disability are strongly linked to mortality in patients with RA, and other independent predictors include age, level of education, comorbidity and use of glucocorticoids. However, whether glucocorticoid use is a marker of disease severity or is in itself deleterious remains unclear.

The major causes of death among patients with RA are cardiovascular and cerebrovascular diseases. Male sex and age at disease onset have been found to predict both the occurrence of cardiovascular events and death. However, it is uncertain whether the results from these previous studies correctly reflect the current mortality risk. Some studies have indicated that RA is now a milder disease than it was several decades ago and also that the disease on average starts later than before. It is also assumed that the advances in treatment strategies and access to new treatments have improved the health of patients with RA. However, it is still important to consider RA as a severe disease with a potential reduction in life expectancy.

2.4.10 Has the disease improved?

To examine changes in disease severity over time potential outcomes include survival, the need for joint replacement surgery, health status and employment. Decreased disease mortality has been reported from Sweden. Data from 47 000 patients were collected from the Swedish Hospital discharge registry. The patients were followed up after 5 and 10 years and this was then linked to the cause of death registry. Compared with patients discharged in the 1960s and early 1970s, patients with RA discharged in the 1980s and 1990s had a significantly reduced mortality rate (Bjornadal et al, 2002). Nevertheless, compared with a matched population, mortality in RA was still doubled, mainly owing to cardiovascular disease. Interestingly, a decreasing mortality for patients in the past two decades was observed.

Despite being considered the most important advance in the management of rheumatic diseases back in the 1980s (Fries, 1989), joint replacement surgery is today an undesirable disease outcome that can be postponed by early administration of disease modifying therapy (Moura et al, 2015). This is based on the notion that early treatment may significantly lower the rate of radiological progression, possibly targeting pathogenetic mechanisms still reversible during the existence of the early therapeutic “window of opportunity” (Kyburz et al, 2011). It is noteworthy that joint surgery other than joint replacement was also delayed in patients from a population-based cohort treated early with DMARDs (Verstappen et al, 2006). These non-joint-replacement

interventions include rheumatoid nodule removal, arthroscopy, carpal tunnel decompression, arthrodesis, synovectomy and resection arthroplasty. In the multivariate analysis, factors associated with risk of joint surgery were higher joint scores (as measures of disease activity) and radiographic progression early within two years following diagnosis (Verstappen et al, 2006).

Several studies demonstrated a decline or at least no change in rates of RA-related joint surgery in the 2000s compared to previous decades, which is in contrast to increasing rates of joint surgery in the general population (mainly due to osteoarthritis)(Jämsen et al, 2013; Sokka et al, 2007; Louie and Ward, 2010). The observed contrast may be ascribed to the increasing use of DMARDs among RA patients – primarily conventional synthetic DMARDs, since data on the role of biologicals in preventing joint surgery still remain scarce. Other plausible explanations may be patient selection towards milder RA cases and natural evolution of RA towards a milder disease (Sokka et al, 2007).

Data from the National Database of the German Collaborative Arthritis Centres show a decrease in disease activity scores for the period between 1997 and 2007, with the number of patients with low disease activity (DAS28 <3.2) having increased from 23% to 49%. At the same time, the intensity of drug treatment increased, with 23% of patients being treated with combinations of DMARDs in 2007 as compared with only 8% a decade earlier. Importantly, this development was paralleled by a strong decrease in the number of annual days of sick leave for each employed person (Ziegler et al, 2010).

A shift to an older age at RA onset has also been reported during the past few years. If patients nowadays develop RA at an older age than previously and if we assume that disease progression is the same, then today's average patient with RA would be spared several years of disease severity in comparison with patients several decades ago. Documentation of improved long-term outcome requires long-term observational data over 10–20 years. Repeated cross-sectional data from the Oslo RA registry in 1994 and 2004 suggest an improved overall health status. For example, the average Modified HAQ score improved from 1.68 in 2001 to 1.58 in 2004. Similar findings were obtained for other dimensions of health status (Heiberg et al, 2005).

Summary Points

- ➔ Joint involvement with a symmetrical small-joint polyarthritis dominates the clinical picture of RA, but extra-articular manifestations may be present both at disease onset and in established disease.
- ➔ The new 2010 ACR/EULAR classification criteria recognise the need to diagnose and treat RA early in order to prevent joint damage and preserve normal functional status.
- ➔ Identification of prognostic markers are as important as the diagnosis of the disease. Elevated acute phase reactants, presence of ACPA and rheumatoid factor, and erosive disease at disease onset, predict persistent erosive arthritis.
- ➔ Several differential diagnoses need to be considered. RA frequently starts after the age of 50, thus generalized osteoarthritis with finger involvement will often be an important consideration. In younger age groups, reactive arthritis and connective tissue diseases need to be considered.
- ➔ RA may result in joint deformities, particularly in the hands and feet. Hand and feet radiographs remain the gold standard in RA imaging, although the use of ultrasonography and MRI is becoming increasingly frequent.
- ➔ Osteoporosis and premature arteriosclerosis are common in RA and are probably related to the inflammatory activity. More data are needed to clarify whether active anti-inflammatory treatment will reduce the frequency of these manifestations.
- ➔ The overall health of RA patients and the burden of disease has improved over the past few decades, which is most likely due to better and more aggressive treatment strategies, and access to better diagnostic, monitoring and treatment modalities.

IN-DEPTH DISCUSSION I

**Measuring disability and health-related quality of life
(HRQoL) in rheumatoid arthritis (RA)**

Summary

Rheumatoid arthritis (RA) can cause severe disability and reduce health related quality of life, aspects that are important to the patients. Thus, it is important to measure disability and health related quality of life in clinical practice and in clinical trials. The aim of this summary is to present an overview of the most important patient self-report instruments that are used to assess disability and health-related quality of life (HRQoL) in patients with RA.

The concepts

Several definitions of disability have been presented. In a recent review, (Leonardi et al, 2006) the following definition has been proposed: "Disability is a difficulty in functioning at the body, person or societal levels, in one or more life domains, as experienced by an individual with a health condition in interaction with contextual factors". HRQoL is a broader concept which can be defined as the impact of health on an individual's ability to function as well as the perceived well-being in physical, mental and social domains of life (Coons et al, 2000). Disability is a subset of HRQoL.

The measurement tools

Questionnaires are used to assess disability and HRQoL. Visual analogue scales (VAS) are widely used to measure pain and fatigue, as well as the patients' global assessment of their disease. Generic instruments with several items have been developed for use in patients regardless of disease. One of the major advantages of such instruments is the opportunity to compare results between disease groups and to compare patients with healthy individuals (Kvien and Uhlig, 2006). Disease specific instruments have typically been developed for use in patients with RA or other arthritic diseases.

Instruments measuring disability

The Stanford Health Assessment Questionnaire (HAQ) (Bruce and Fries, 2005) was introduced in the 1980's and is now widely used in evaluation of patients with RA. It was initially developed for use in rheumatology, but has later also been applied to other diseases. Some investigators will therefore argue that HAQ can be considered a generic instrument.

The disability index includes questions about the ability of patients to perform 20 activities of daily living, and is most commonly referred to as the HAQ-questionnaire, and sometimes as the HAQ-disability index (HAQ-DI). Four response categories are available for each question; without any difficulty (score 0), with some difficulty (score 1), with much difficulty (score 2) or unable to do (score 3). The 20 activities are classified into eight categories with two or three activities each. A score is then assigned to each of the eight categories based on the highest score of the items within the category. Patients are also asked about use of aids and devices, and if

they need help from another person for activities in any of the eight categories. If category score is lower than two, it is increased to two within any category in which the patient uses a device or help from another person, so that the underlying disability is more accurately represented. It is important to note that HAQ scores without this adjustment will be lower than the scores obtained with the original scoring system. The total HAQ score, with range 0-3, is the mean of the scores for the eight categories (Bruce and Fries, 2005).

The Modified Health Assessment Questionnaire (MHAQ) (Pincus et al 1983) keeps one question from each of the eight categories in the HAQ and reduces the number of items to eight. No adjustment of scores is possible. The total MHAQ score is the mean of the scores for each activity. MHAQ can easily be administered in clinical practice, but will provide lower scores than HAQ, especially for patients with high disease activity.

A multidimensional health assessment questionnaire (MDHAQ) (Pincus et al, 1999) includes more items, such as demanding physical activities, pain, fatigue, anxiety and depression. The aim of this instrument is to be able to measure disability in patients with healthier conditions and avoid the ceiling effect of HAQ and MHAQ in patients with limited disability. Furthermore, the MDHAQ was developed as a comprehensive measure of disability in a short and user-friendly format and also included questions on other dimensions of health, including stress, anxiety and depression.

Profiles and utility instruments measuring Health Related Quality of Life

There are two main groups of instruments measuring Health Related Quality of Life (HRQoL): Profiles and Utility instruments. A profile contains separate scores for several dimensions. A utility score provides only one sum score for each patient on a scale from 0.0 (a health state similar to death) and 1.0 (perfect HRQoL). Some of the instruments also allow values below 0.0, representing health states that are considered worse than death.

SF-36 (Ware and Sherbourne, 1992) is the most widely used generic health status measure. It is used in health surveys in the general population as well as in various disease populations. The 36 items in the questionnaire are grouped into eight multi-item subscales measuring physical functioning (10 items), role limitations due to physical health (4 items), bodily pain (2 items), general health (5 items), vitality/energy/fatigue (4 items), social functioning (2 items), role limitations due to emotional problems (3 items), mental health (5 items), plus one item on reported health transition. Each scale is expressed with values from 0-100 and a low score indicates poor health. One particular advantage of SF-36 is that it also includes a scale on energy/vitality, a dimension which is considered important by patients. The domain concerning physical functioning is based on 10 items regarding limitations in physical activities because of health problems, but none of these items directly addresses dexterity, which is important in RA.

The EQ-5D (Brooks, 1996) is the most widely used utility instrument and captures five health dimensions (mobility, self-care, usual activity, pain/discomfort and anxiety/depression), with three response categories within each of these dimensions; no problems, some or moderate problems and extreme problems (Brooks, 1996). EQ-5D encompasses 243 different health states (Rasanen et al, 2006). One reason for the widespread use may be that EQ-5D is easy to use with only five questions.

SF-6D is a relatively new utility instrument where some of the answers from SF-36 and SF-12 can be recalculated into a utility score (Brazier et al, 2002). The opportunity to recalculate answers from SF-36, which is already measured in many clinical trials, makes it possible to reduce the amount of questionnaires in studies.

Disease specific profiles

The Arthritis Impact Measurement Scales (AIMS) was developed in 1980 to measure the health status of patients with arthritis (Meenan et al, 1980) with 7 demographic items and 55 health status items. It was later revised into the AIMS2 which is an expanded version of AIMS with 78 items capturing information in 12 areas of health (mobility level, walking and bending, hand and finger function, arm function, self-care tasks, household tasks, social activity, support from family and friends, pain, work, level of tension, mood) (Meenan et al, 1992). These twelve scales can be aggregated into 5 major dimensions (physical functioning, social interaction, pain, work and affect). The score is from 0 to 10 (10 being worst possible health).

The Rheumatoid Arthritis Quality of Life questionnaire (RAQoL) is a RA-specific quality of life measure that comprises 30 statements about unfulfilled needs related to activities relevant to patients (de Jong et al, 1997). Each question is answered with Yes or No. Possible scores range from 0 to 30, the higher score representing worse quality of life.

Clinical meaning of disability and HRQoL in RA

Disability is one of the most important outcomes in RA. Decreased functional status (disability) assessed by HAQ has been identified as the most important predictor of mortality in two studies carried out for over two decades in patients with RA (Wolfe et al, 2003; Yelin et al, 2002). Disability is also associated with work incapacity, representing an important burden for the RA patient and the society (Callahan et al, 1992).

RA-related disability comprises two components: a reversible activity-related component and an irreversible component depending on the extent of damage accrual (Aletaha et al, 2006). The activity-related component is driven by pain and stiffness (Smolen and Aletaha, 2009), whereas the irreversible component, interestingly, is primarily a consequence of cartilage destruction (radiologically detected as joint space narrowing) rather than of bone erosions (Aletaha et al, 2011). According to this model, irreversible disability should equal the level of disability determined after achieving a defined treatment target such as low disease activity or, ideally,

remission. However, improvement of physical function over time has been observed even if the target was achieved and maintained thereafter (Radner et al, 2015). Although this effect may seem contradictory to the “floor effect” of irreversible disability persisting after achieving remission, it might be a consequence of improved residual activity over time and, possibly, recovery of joint mobility, muscle strength and fatigue.

RA is responsible for only a portion of overall disability in patients with RA. At least three other determinants have been identified as contributors to disability in RA: comorbidities, mental health and age (Smolen and Aletaha, 2009). In a study by Radner et al., comorbidities influenced disability independent of RA activity and other disease characteristics (Radner et al, 2010). After achieving remission, a “floor effect” was described, i.e. a residual level of irreversible disability ascribed not only to RA-related damage but also to comorbidities. The observed effect was independent of the instrument used, i.e. the HAQ as a measure of disability or SF-36 as a HRQoL measure (Radner et al, 2010). Furthermore, a higher burden of comorbidities led to increased disability in each domain of the HAQ and to decreased HRQoL as determined by the physical component score of the SF-36. On the other hand, the mental component score of the SF-36 was not influenced by comorbidities (Radner et al, 2011).

Of note, comorbidities were identified in 32% of patients with recently diagnosed RA in an inception cohort from the UK, while their 15-year cumulative incidence was 81% (Norton S et al, 2013). Comorbidities have been associated with an increased risk of all-cause and cardiovascular mortality, as well as a 10-year decline in functional status. Given the association of disability with increased mortality, and the fact that disability is – to a large extent – driven by comorbidities, comorbidities may be the link between disability and increased mortality in RA (Smolen and Aletaha, 2009; Radner et al, 2010). According to a recent systematic review and meta-analysis (Matcham et al, 2014), RA negatively affects overall HRQoL measured by SF-36, as well as its physical (to a greater extent) and mental health components (to a lesser extent). Both of these components are lower in patients with RA compared to the general population, but also - even more strikingly – lower compared to patients with some of the most important causes of morbidity: hypertension, congestive heart failure, type 2 diabetes mellitus and myocardial infarction. Higher age has been associated with lower physical functioning and, interestingly, with a higher score in the mental health domain. The latter effect may be a consequence of a greater impact of the disease on self-realization at a younger age.

Due to their clinical importance and prognostic implications, disability and HRQoL should be regularly assessed throughout the follow-up of patients with RA. They should be taken into account when making clinical decisions, in addition to assessment of disease activity (Smolen et al, 2016).

In summary,

- Questionnaires assessing health have been shown to be useful and important in clinical trials as well as to monitor disease course in clinical practice and to predict important outcomes.
- The choice of instrument should be based on the situation and the goals of the use. Instruments that have been validated should be chosen to optimize the results.
- Disability is comprised of a reversible portion associated with RA disease activity and an irreversible portion resulting from accrued damage and comorbidities.
- Both disability and comorbidities have been described as important predictors of mortality in patients with RA.
- The physical and mental health components of HRQoL are lower in RA than in other important causes of morbidity in the general population, such as myocardial infarction, congestive heart failure and type II diabetes mellitus.

IN-DEPTH DISCUSSION II

Cytokines and rheumatoid arthritis

Cytokines are small molecular weight mediators of cell-cell communication and include interleukins (ILs), interferons, growth factors, colony-stimulating factors, and other groups. These molecules are released by a variety of cells and usually act locally in a tissue to affect adjacent cells in a paracrine manner. Cytokines also may act inside a cell (intracrine), affect the same cell after release (autocrine), or travel through the circulation to act at a distance in an endocrine manner (i.e. IL-6 and the activation of acute-phase proteins by hepatocytes). Extensive data has been accumulated over the last 20 years to implicate various cytokines in the pathophysiology of rheumatoid arthritis and other rheumatic diseases. Abnormalities in cytokine production are not the cause of these diseases, but reflect continuous production by immune and inflammatory cells.

An important principle to emerge is that chronic inflammatory disease may result from the excess production of pro-inflammatory cytokines and/or the inadequate production of anti-inflammatory cytokines or factors (Mateen et al, 2014). Amongst other cells, macrophages and CD4-positive T lymphocytes play a major role in the production of pro-inflammatory cytokines within the inflamed synovial membrane (Szekanecz, 2007). Pro-inflammatory cytokines with the most prominent role in the inflammation of RA, also serving as targets of successfully used biological therapies, are tumour necrosis factor (TNF)- α and IL-6. They mediate processes inherent to the innate immune response: endothelial activation, migration of leukocytes towards the synovial tissue, activation of fibroblast-like synoviocytes (FLSs) and chondrocytes, angiogenesis and nociception. Furthermore, they are responsible for RA-associated structural damage by activation of osteoclasts (McInnes et al, 2016). IL-6 is directly involved in the acute phase response, it is considered the main driver of anemia of chronic disease (Raj, 2009) and might be associated with an increased cardiovascular risk (McInnes et al, 2015). Additionally, IL-6 has a prominent role in adaptive immunity, regulating the differentiation of naïve T cells towards proinflammatory Th17 cells or anti-inflammatory T regulatory (Treg) cells (McInnes et al, 2016). TNF- α is also involved in adaptive immunity, stimulating proliferation and differentiation of lymphocytes and inducing pro-inflammatory cytokines and other molecules (Mateen et al, 2016).

Members of the IL-1 cytokine family also have a prominent place in inflammation and osteoclast activation in RA, with their role overlapping with the role of TNF- α in innate immunity (Kay and Calabrese, 2004). However, contrary to the clinically effective inhibition of TNF- α and IL-6 receptor, targeting IL-1 has not shown to lead to meaningful clinical results.

GM-CSF and its receptor have been identified as novel targets in the treatment of RA. Granulocyte-macrophage colony stimulating factor (GM-CSF) promotes activation, differentiation and survival of macrophages and neutrophils, promoting their pro-inflammatory activity (Cornish et al, 2009). Mavrilimumab, a monoclonal antibody against GM-CSF receptor has shown to significantly reduce disease activity and improve disability in a phase 2 randomized double-blind study (Burmester et al, 2013).

Several other cytokines present in the rheumatoid synovium are also likely to contribute to the pathogenesis of RA (Table 1 and Figures 1 and 2). The IL-23/IL-17 pathway is potentially involved in the pathogenesis of arthritis (reviewed in Gabay, 2009; Lubberts, 2015; Roeleveld and Koenders, 2015; Mateen et al, 2016). IL-23 is a heterodimeric protein that belongs to the IL-12 family of cytokines. In addition to its specific subunit, p19, it shares a common p40 unit with IL-12. IL-23 stimulates the polarization of Th17 cells and the production of IL-17. It also directly stimulates osteoclastogenesis. Activated synovial macrophages represent a source of IL-23. IL-17, on the other hand, may induce the production of IL-23 by synovial fibroblasts, thus activating a positive feedback loop. Furthermore, IL-17 stimulates the production of IL-1, TNF α , and IL-6 by human monocytes and of IL-6 by rheumatoid synovial fibroblasts. The combination of IL-17 and TNF- α exhibits synergistic stimulation of IL-1 β , IL-6, and IL-8 (also termed CXCL8) production in rheumatoid synovial fibroblasts. The broad effects of IL-17 include promoting persistent disease and supporting angiogenesis by stimulating fibroblast like synoviocytes to produce vascular endothelial growth factor (VEGF). IL-17 also promotes tissue damage by inducing the production of matrix metalloproteinase in human monocytes and their derivatives in synovial tissue, as well as the differentiation of osteoclasts leading to bone degradation. In addition to Th17 cells, IL-17 is also produced by lymphocytes, neutrophils and mast cells within arthritic synovial tissues. Th17 cells also secrete TNF- α and GM-CSF, therefore playing a role in both the innate and adaptive immunity. Blocking IL-23 and IL-17 ameliorates the severity of collagen-induced arthritis.

Serum and synovial fluid IL-17 levels correlate with markers of acute phase response, disease activity and structural damage. However, clinical trials of agents targeting the IL-23 or IL-17 have not shown sufficient clinical efficacy in patients with RA (Lubberts, 2015). One IL-17A inhibiting antibody – ixekizumab – exerted only a limited effect on disease activity, symptoms and acute phase parameters, while the other – secukinumab – did not achieve an effect in the short term, despite slightly better results noted in the prolonged treatment course. Even more disappointingly, brodalumab, an anti-IL-17 receptor (IL-17RA) antibody, as well as ustekinumab and guselkumab – monoclonal antibodies targeting IL-23, failed to show a clinically relevant effect in RA (Semerano et al, 2016). These findings may be explained by the existence of specific disease subtypes responding specifically to IL-17 targeting, but also by a redundancy in the effects mediated by different cytokines involved in RA. To that end, since TNF- α and IL-17 seem to act synergistically, concomitant blockade of both cytokines may prove to be therapeutically useful (McInnes et al, 2016). It is noteworthy that biological agents already successfully used in the treatment of RA – abatacept, tocilizumab, tofacitinib and rituximab - have been associated with a decline in the number of Th17 cells and, in turn, of IL-17 levels (Roeleveld and Koenders, 2014).

IL-22 is another proinflammatory cytokine produced by Th17 cells. Its levels positively correlate with RF and ACPA titers. Furthermore, its presence is significantly associated with erosive arthritis (Roeleveld and Koenders, 2015; Lubberts E, 2015).

IL-12 released by macrophages or dendritic cells through innate immune mechanisms regulates the polarization of Th1 cells and the production of IFN- γ by Th1 and NK cells (reviewed in Mateen et al, 2012). Results of studies including paired synovial fluid and serum samples showed that IL-12 is produced in inflamed joints. In addition, IL-12 levels correlate with disease activity, and decrease in serum and synovial fluid following DMARD therapy. IL-18 is also produced by macrophages and dendritic cells and acts in synergy with IL-12 to stimulate IFN- γ production by Th1 and NK cells. IL-18 is also produced by synovial fibroblasts in response to IL-1 and TNF- α , thus contributing to a positive feedback loop. IL-18 acts as a chemo attractant for T cells and as an angiogenic factor. It has a natural antagonist, IL-18 binding protein (IL-18BP). Administration of recombinant IL-18BP inhibited the development and severity of collagen-induced arthritis, thus supporting the role of IL-18 in experimental arthritis. IL-15 is present in high concentrations in rheumatoid synovial fluid and can also be found in the synovial membrane where it appears to be produced by macrophages, T cells and NK cells. IL-15 activates T cells to induce TNF- α production in macrophages through cell-cell interactions, and stimulates synovial fibroblasts to proliferate and resist apoptosis. Thus, the effects of IL-15 in the rheumatoid synovium result in the activation of T cells, macrophages and fibroblasts (Yang et al, 2015). In addition to proinflammatory cytokines, the rheumatoid synovium is also a source of Th2 and regulatory cytokines including IL-4, IL-10, IL-1 receptor antagonist (IL-1Ra) and transforming growth factor (TGF)- β (Mateen et al, 2016; Alunno et al, 2015). The latter also has positive effects on tissue repair. However, the production is insufficient to counterbalance the effect of pro-inflammatory cytokines, leading to the perpetuation of the inflammatory process. Strikingly, recent evidence revealed a potential anti-inflammatory role of TNF- α , mediated via its RII receptors (unlike its inflammatory actions mediated via RI receptors). One of the most important anti-inflammatory actions mediated by TNF- α is differentiation of Treg cells from its precursors - naïve T helper cells (Alunno et al, 2015).

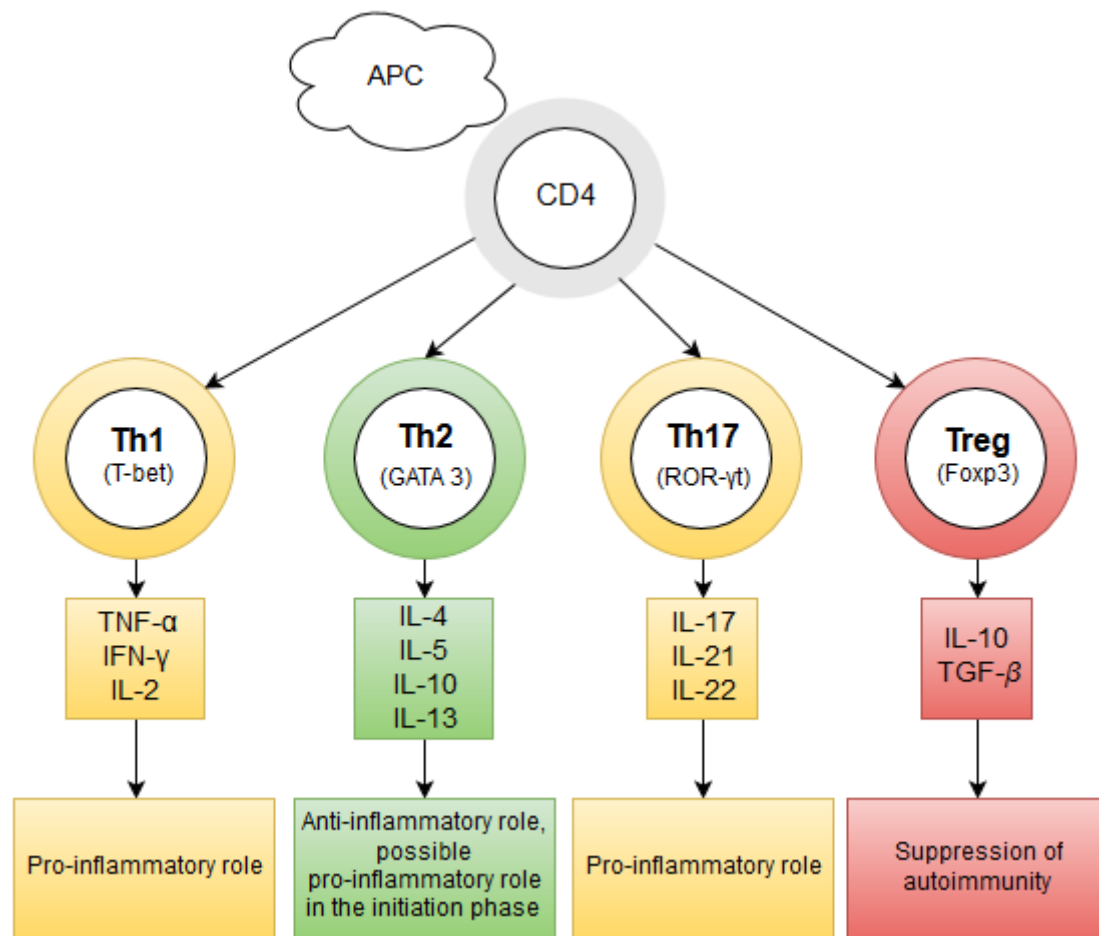

The profile of cytokines present in the rheumatoid synovial tissue varies according to the stage of the disease. Notably, patients with early arthritis (symptom duration less than 3 months) that progressed to RA exhibited a different synovial cytokine profile than patients that remitted or developed other arthritides (Raza K, 2005). The absence of the Th1-cytokine interferon (IFN)- γ and the presence of Th2-cytokines IL-4 and IL-13 together with (presumably) Th17-derived IL-17 in early RA, favour an important role for T cells – in particular Th2 and Th17 cells, in the initiation phase of RA.

Finally, it is important to mention that distinct cytokine profiles were found to correlate with subtypes of lymphocyte infiltration in active RA. The major histological pattern of diffuse synovitis was marked by low-level transcription of genes for IFN γ , IL-4, IL-1 β , and TNF α . Follicular synovitis was the next most common pattern with the presence of abundant IL-10. Lastly, granulomatous synovitis was characterized by high levels of transcription of IFN γ , IL-4, IL-1 β , and TNF α (Klimiuk PA, 1997).

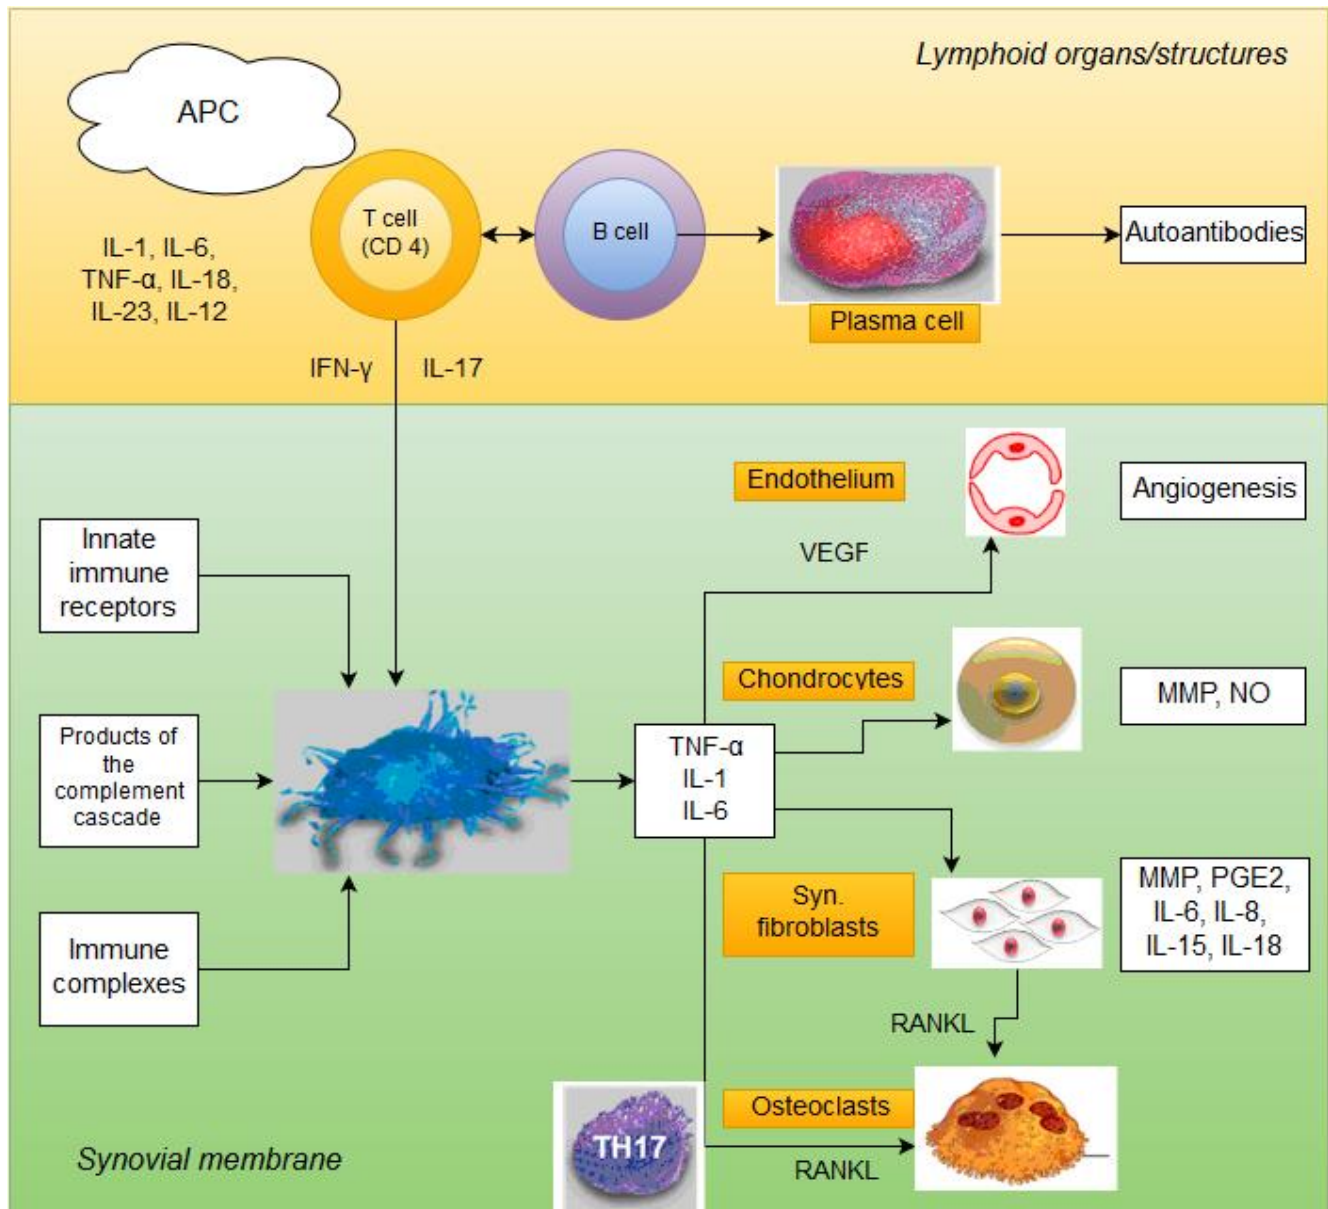

Table 1. Cellular source and functions of cytokines

Cytokines	Main cellular source	Function
TNF- α	macrophages/T cells	Pro-inflammatory, recruitment of inflammatory cells, endothelial, chondrocyte and synovial cell activation, cartilage and bone degradation (Th1 response)
IL-1	macrophages	Similar to the role of TNF- α
IL-1Ra	macrophages	Anti-inflammatory (inhibitor of IL-1)
IL-6	macrophages/stromal cells	Pro-inflammatory, stimulates T cells (Th17) and B cell activator, induces acute phase response and anemia of chronic disease
IL-8 (CXCL8)	macrophages/stromal cells	Pro-inflammatory/recruitment of neutrophils, pro-angiogenic
GM-CSF	lymphocytes	Pro-inflammatory, activation of macrophages and neutrophils
IL-23	macrophages/dendritic cells	Stimulates Th17 responses (see IL-17 below), osteoclastogenesis
IL-17	T cells/mast cells/neutrophils	Pro-inflammatory, support of disease persistency and perpetuation of the inflammatory state, angiogenesis, bone damage (Th17 responses)
IL-22	T cells	Osteoclast activation
RANK ligand	synovial fibroblasts/T cells	Osteoclast activation
IL-12	macrophages/dendritic cells	Stimulates Th1 (IFN- γ) responses
IL-18	macrophages/dendritic cells	Pro-inflammatory/stimulates Th1 (IFN- γ) responses and NK cells
IL-15	macrophages/stromal cells	Pro-inflammatory, activates T and NK cells
Interferon (IFN)- γ	T cells/NK cells	Th1 responses/activation of macrophages
IL-4	T cells/basophils	Promotion of humoral immunity and inhibition of the Th1 response (Th2 responses)/anti-inflammatory in models of arthritis
IL-10	macrophages/T cells	Anti-inflammatory
TGF- β	macrophages/stromal cells	Anti-inflammatory, Treg expansion (but Th17 in presence of IL-6), tissue repair, fibrosis

This table represents some of the main cytokines involved in the pathogenesis of arthritis as demonstrated in animal models and/or in human RA.

Figure 1. Major subsets of CD4⁺ T lymphocytes involved in the pathogenesis of RA

Naïve CD4 cells are activated by antigenic peptides presented by HLA II molecules by antigen presenting cells (APC). Activated CD4 T cells differentiate into at least four different phenotypes depending on the local cytokine milieu: Th1, Th2, Th17 and regulatory T cells (Treg). Distinct markers of each cell phenotype are indicated in parentheses. Each cell type produces a set of signature cytokines and has a specific role in the autoimmunity of RA. While Th1 and Th17 responses have a pro-inflammatory role, Th2 and the regulatory T cell responses play a counter-regulatory role, with the Th2 response counterbalancing Th1 and the Treg counterbalancing the Th17 response (Th1/Th2 and Th17/Treg dichotomy).

Figure 2. Dissecting the immune response in RA

The activation of adaptive immune responses take place primarily in lymphoid organs or lymphoid structures within the rheumatoid synovium. T cells are activated by antigen presenting cells (APC) which release cytokines inducing the polarization of T cells into T helper 1 (Th1) or Th17 cells producing interferon-gamma (IFN- γ) and IL-17, respectively. T helper cells contribute to the maturation of B cell responses and autoimmune responses leading to the production of autoantibodies, including rheumatoid factors (RF) and anti-citrullinated protein antibodies (ACPA). In the synovial membrane, macrophages can be activated by different stimulants including immune complexes, products of the complement cascade (via complement receptors), activated T cells, and innate immune receptor ligands, leading to the release of pro-inflammatory cytokines such as TNF- α , IL-1 and IL-6. These cytokines stimulate 1) endothelial cells leading to enhanced expression of adhesion molecules and angiogenesis (this effect is also mediated by vascular endothelial growth factor (VEGF) and some chemokines), 2) articular chondrocytes to release matrix metalloproteinases (MMP) and nitric oxide (NO) leading to cartilage breakdown, 3) synovial fibroblasts to release cytokines, prostaglandin E₂ (PGE₂), and other inflammatory agents as well as MMP, and 4) directly and indirectly the maturation and activation of osteoclasts leading to

bone erosions. Synovial fibroblasts and T cells secrete also RANK ligand (RANKL) and contribute to the stimulation of osteoclasts.

Treatment of rheumatoid arthritis

Bruno Fautrel, Stéphane Mitrovic, Peter Taylor

A previous version was co-authored by Peter Taylor, Elsa Vieira-Sousa, João Eurico Fonseca

LEARNING OUTCOMES

- To know the general approach to the patient with rheumatoid arthritis (RA).
- To know the concepts of window of opportunity, treatment to target and tight control.
- To know the range of agents available to treat RA and to be familiar with the major indications for, and toxicities of, conventional synthetic and biological disease-modifying antirheumatic drugs.
- To know the emerging role of targeted therapies in the treatment of RA.
- To know the optimal strategic approaches to disease management aiming at early remission or low disease activity states
- To know the main clinical studies that have contributed to RA care improvement (*Appendix 1*)
- To know how to adjust RA treatments before and during pregnancy and lactation (*Appendix 2*)
- To be familiar with the vaccination recommendations in RA (*Appendix 3*)
- To be able to detail the role played by allied health professionals in the treatment of RA (*In-Depth Discussion 1*)
- To be familiar with the major indications for, and toxicities of, analgesics, Non-Steroidal Anti-Inflammatory drugs (NSAIDs) and steroids (*In-Depth Discussion 2*).
- To be able to explain the concept of “bridging therapy” for steroids, and to be familiar with their structural effect (*In-Depth Discussion 2*).
- To be familiar with the local and non-pharmacological therapeutics (local steroid injections, radioisotopic synoviorthesis, rehabilitation, splints, orthoses, and braces, surgery, cervical spine management) (*In-Depth Discussion 3*).

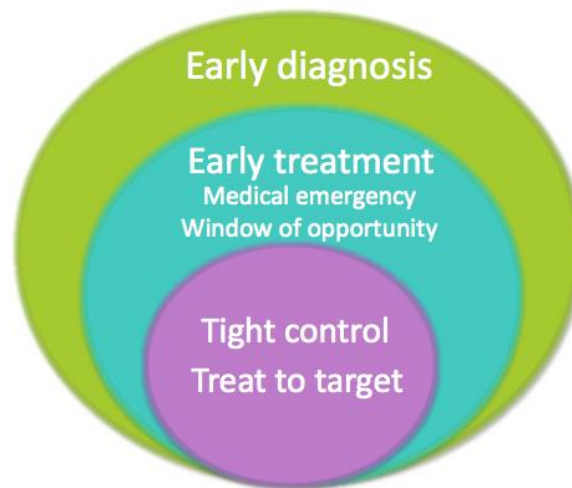

Introduction

The treatment of rheumatoid arthritis (RA) has remarkably evolved over the past 20 years. Indeed, for many decades, the therapeutic approach was to adopt a cautious “wait and see” strategy at the initial steps of the disease to keep the most effective – or the least ineffective – therapies for more advanced stages. The pyramidal strategy proposed at that time (Fries et al. 1990) placed first non-pharmacological (physiotherapy, occupational therapy, rest and rehabilitation, education) and symptomatic treatments (painkillers and non-steroidal anti-inflammatory drugs or NSAIDs), with use of steroids for intense flares. Disease Modifying Anti-rheumatic Drugs (DMARDs) – mainly Gold salts or D-penicillamine at that time – or other immunosuppressant drugs were to be introduced later in the disease course. In addition, the decision to change therapy was generally driven by either physician (occasionally patient) perception of efficacy or by toxicity, without any formal assessment of disease activity due to the lack of validated composite measures. Thus, this approach is clearly identified as non-optimal nowadays since it did not address the 3 main disease consequences:

- Severe disability due to progressive and extensive joint damage,
- Substantial morbidity related to disease-related cardiovascular disorders or drug side effects (infections, drug allergy, osteoporosis)
- Increased mortality due to cardiovascular events or infections.

During the 1990s, RA care has evolved as the results of the implementation of 3 main paradigms (**Figure 1**):

- 1/ Improvements in the diagnosis of RA at an early stage, which has been facilitated by the development of new classification criteria (ACR/EULAR 2010, Aletaha ARD 2010);
- 2/ The demonstration of a need for early treatment as soon as RA diagnosis – “RA is a medical emergency”, as diabetes mellitus or hypertension (T Pincus 1994) – and the identification of “window of opportunity” for RA treatment (P Emery 2002);
- 3/ The development of the notion of RA “tight control” in which therapeutic adjustments have to be based on an validated composite measure of RA disease activity – somehow equivalent to blood pressure in hypertension or glycosylated haemoglobin in diabetes mellitus – (J Smolen, 2010) and the definition of remission or low disease activity as ultimate goal (J Smolen, 2013 et 16);

Figure 1: The 3 main paradigms of RA care

In addition, there was a substantial increase in the number of therapeutic agents (DMARDs) able to modify the natural evolution of RA, either at the joint level (inflammation and damage) or at the systemic level (reduction in cardiovascular morbidity and mortality).

1/ Early RA diagnosis

The first challenge for the physician is to make an early diagnosis. This one should be ideally made by the rheumatologist: patients presenting joint swelling associated with pain and morning stiffness of at least one joint should be referred to and seen by a rheumatologist, ideally within six weeks after the onset of symptoms (Combe, 2007). Making the diagnosis of RA is a quite difficult task and should include:

- the recognition of a rheumatic inflammatory disorder compatible with RA (the ACR/EULAR 2010 classification criteria might be of help, Aletaha ARD 2010)
- the exclusion of differential diagnoses, which differ in patients with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis or gout (Aletaha ARD 2010);
- the identification of patients at risk of developing persistent and/or erosive arthritis (Combe, 2007).

2/ RA as a medical emergency and the notion of a “window of opportunity”

The better understanding of the RA pathogenesis, as well as RA joint and systemic consequences, has led to recommend an as early as possible therapeutic intervention. RA became a “medical emergency” (T Pincus, 1995) as diabetes or hypertension, indicating that treatments have to be started as soon as the diagnosis and not when the first consequences of the diseases occur (stroke, renal insufficiency or visual loss for example). One of the most convincing elements to support such a recommendation was the demonstration that joint damage starts as soon as the first weeks or months of the disease: the majority of patients (75%) develop erosive disease within the first two years of the disease, and the rate of progression (expressed as newly eroded joints or increase in radiographic damage) is the highest during the early years of the disease (Van Der

Heijde, 1995) (figure 2).

Figure 2: Rapidity of erosive disease onset in patients with early RA (van der Heijde 1995).

The development of such erosions constitutes the basis of RA-induced “irreversible damage”, as opposed to synovial inflammation which remains accessible to modern therapies throughout RA course. To start treatment in the early phase of the disease represents a unique **window of opportunity** for an efficacious treatment in order to completely block synovial inflammation and prevent the development of synovial hypertrophy and joint damage (**Figure 3a**). Delaying DMARD therapy for as little as 8 or 9 months after initial diagnosis appears to directly contribute to functional and radiographic deterioration in patients with RA (Smolen, 2002). The existence of this window of opportunity was attested by a work on the results of the Leiden Early Arthritis Clinic (LEAC) and ESPOIR cohorts, in which the start of the treatment within the first 12 weeks of the disease is associated with a higher chance to achieve RA drug-free remission (Van Nies et al. 2015) (**Figure 3b**).

Figure 3a: Relation between delay of the therapeutic intervention and the effect on inflammation and joint damage/loss of function (Emery P, 2002).

Figure 3b: Relation between the probability of achieving drug-free remission in early RA patients and the delay of DMARD initiation after RA onset in the ESPOIR cohort (Van Nies et al. 2015).

3/ “Tight control” and “treat to target (T2T)”

During the last 2 decades, several disease activity measures have been proposed: the Disease Activity Score (DAS) 28, which is a disease activity score using 28 joint counts along with other components in a complex calculation (MLL Prevoo, 1995); the simplified disease activity index (SDAI, JS Smolen, 2003) and clinical disease activity index (CDAI, D Aletaha, 2005) which provide continuous numerical scales reflecting disease activity (higher is worse) (**Table 1A & B**). These measures can classify disease activity states (high, moderate, low and remission). Thanks to these tools, EULAR as well as ACR guidelines recommended to use composite measures to assess RA patient disease activity in daily care in order to make regular adjustment of DMARDs – i.e., disease tight control – and be able to achieve the optimal and consensual therapeutic goal: remission or at least low disease activity – i.e., treat to target (*Felson DT, 2011).

These statements were based on several randomized controlled trials and a metaanalysis that demonstrated that dynamic strategies based on these 2 notions were more effective than usual care, i.e., not disease activity-driven (Schipper LG et al. 2010; Schipper et al, 2012) (**Figure 4**).

Figure 4: Benefit of a DAS28-driven dynamic strategy (tight-control) over usual care in a 1-year randomized controlled trial (Schipper et al. 2012)

a. Evolution of mean DAS28 in the 2 arms

b. Time to achieve DAS28 remission in the 2 arms

The wide implementation of such principles have been associated with RA prognosis improvement, with less overall disability, reduction in the need of orthopaedic surgery, reduction of sick day as well as improvement in cardiovascular morbidity and mortality.

Table 1A: Composite measures of disease activity including joint counts, and ACR-EULAR remission criteria

Components		Cutpoints			
		Remission	Low disease activity	Moderate disease activity	High disease activity
DAS28-ESR*	Tender joint count (of 28)	< 2.6	2.6 to	> 3.2 to ≤ 5.1	> 5.1
	Swollen joint count (of 28)		3.2		
	Erythrocyte sedimentation rate (in mm)				
	Patient global assessment (0-100 VAS)				
DAS28-CRP†	Tender joint count (of 28)	< 2.6	2.6 to	> 3.2 to ≤ 5.1	> 5.1
	Swollen joint count (of 28)		3.2		
	C-reactive protein (in mg/dL)				
	Patient global assessment (0-100 VAS)				
SDAI‡	Tender joint count (of 28)	≤ 3.3	> 3.3 to	> 11 to ≤ 26	> 26
	Swollen joint count (of 28)		11		
	Patient global assessment (0-10 VAS)				
	Physician global assessment (0-10 VAS)				
CDAI§	Tender joint count (of 28)	≤ 2.8	> 2.8 to	> 10 to ≤ 22	> 22
	Swollen joint count (of 28)		10		
	patient global assessment (0-10 VAS)				
	physician global assessment (0-10 VAS)				
ACR-EULAR remission	SDAI	SDAI ≤ 3.3			
	CDAI	CDAI ≤ 2.8			
	Boolean: swollen joint count (of 28), tender joint count (of 28), patient global assessment (0-10 VAS), C-reactive protein (in mg/dL)	Boolean all ≤ 1			

Patient global assessment reflects global health in DAS 28; mm in DAS 28; cm in CDAI, SDAI, Boolean.

ACR=American College of Rheumatology. EULAR=European League against Rheumatism. DAS28=disease activity score using 28 joint counts. SDAI=simplified disease activity index. CDAI=clinical disease activity index. TJC28=tender joint count (of 28). SJC28=swollen joint count (of 28). ESR=erythrocyte sedimentation rate (in mm). GH=global health. CRP=C-reactive protein (in mg/dL); *DAS28-ESR calculated according to the following equation: $0.56 \times \sqrt{TJC28} + 0.28 \times \sqrt{SJC28} + 0.70 \times \log_e(ESR) + 0.014 \times GH$. †DAS28-CRP calculated according to the following equation: $0.56 \times \sqrt{TJC28} + 0.28 \times \sqrt{SJC28} + 0.36 \times \log_e(CRP+1) + 0.014 \times GH + 0.96$ ‡SDAI calculated according to the following equation: $TJC28 + SJC28 + PtGA + EGA + CRP$.

§CDAI calculated according to the following equation: $TJC28 + SJC28 + PtGA + EGA$

Table 1B: ACR response criteria and ACR-EULAR remission criteria

	Components	Definition
ACR-EULAR remission	Index: SDAI, CDAI; Boolean: swollen joint count (of 28), tender joint count (of 28), patient global assessment, C-reactive protein (in mg/dL)	SDAI ≤ 3.3 CDAI ≤ 2.8 Boolean all ≤ 1
ACR20 Response	Tender joint count, Swollen joint count, ESR or C-reactive protein (in mg/dL), Pain on VAS, Patient global assessment, Physician global assessment, functional capacity on HAQ	Improvement of 20% of - TJC - SJC - AND of 3 of the 5 others
ACR50 Response	Tender joint count, Swollen joint count, ESR or C-reactive protein (in mg/dL), Pain on VAS, Patient global assessment, Physician global assessment, functional capacity on HAQ	Improvement of 50% of - TJC - SJC - AND of 3 of the 5 others
ACR70 Response	Tender joint count, Swollen joint count, ESR or C-reactive protein (in mg/dL), Pain on VAS, Patient global assessment, Physician global assessment, functional capacity on HAQ	Improvement of 70% of - TJC - SJC - AND of 3 of the 5 others
ACR Non response	Tender joint count, Swollen joint count, ESR or C-reactive protein (in mg/dL), Pain on VAS, Patient global assessment, Physician global assessment, functional capacity on HAQ	Absence of ACR20 response

*It is worthy of note that ACR (American College of Rheumatology) distinguish a change from baseline of several defined variables by at least 20% (ACR20, minimal response), 50% (ACR50, moderate response) or 70% (ACR70, major response) (Felson, 1995) (Table 1b). However, the ACR criteria have been developed to differentiate active therapy from placebo in clinical trials (in particular, ACR20), but cannot be used in practice (on the contrary of ACR-EULAR criteria) because they are not based on a continuous scale (improvement is related to baseline values of the respective variable, which differ between individual patients or within patients at different treatment starts) (*Smolen, 2016).*

1. Pharmacological treatment in RA

1.1 Overview of Disease-Modifying Antirheumatic Drugs (DMARDs)

DMARDs constitute the backbone of RA pharmacological treatment, and all patients with RA are candidates for DMARD therapy. These agents are commonly characterised by their capacity to:

- reduce or reverse RA signs and symptoms as well as acute phase response,
- slow down or stop joint damage progression,
- reduce consequences of systemic inflammation and physical limitation, mainly cardiovascular diseases.

By these actions, they limit long-term disability, improve quality of life and ability to work, and thus interfere with the entire disease process (Smolen et al. 2007).

DMARDs form two major classes: synthetic chemical compounds (sDMARDs) and biological agents (bDMARDs). In light of the recent emergence of new therapeutics (such as kinase inhibitors and biosimilars), a new nomenclature was recently proposed, and adopted by the EULAR Task Force in the 2013 and 2016 recommendations (Smolen et al, 2014; *Smolen et al, 2014; Smolen et al, 2016). Consequently, the term conventional sDMARDs (csDMARDs) are now used to include chemical agents such as methotrexate (MTX), sulfasalazine and leflunomide, whereas tofacitinib, a new sDMARD specifically designed to target janus kinases (JAKs), is designated as a targeted sDMARD (tsDMARD). The five available tumour necrosis factor (TNF) inhibitors (adalimumab, certolizumab pegol, etanercept, golimumab and infliximab), the T cell costimulation inhibitor, abatacept, the anti-B cell agent, rituximab, and the interleukin (IL)-6 receptor (IL-6R)-blocking monoclonal antibody, tocilizumab, as well as the IL-1 inhibitor, anakinra, are subsumed as biological originator (bo) DMARDs, while biosimilars (bs), such as bs-infliximab, recently approved by the European Medicines Agency (EMA), are named bsDMARDs (table 2).

Table 2. Nomenclature of disease-modifying antirheumatic drugs, proposed by Smolen et al., and adopted by the EULAR Task Force in the 2013 recommendations (Smolen et al. 2014, *Smolen et al. 2014).

Disease Modifying Antirheumatic Drugs (DMARDs)			
Synthetic DMARDs (sDMARDs)		Biological DMARDs (bDMARDs)	
Conventional synthetic DMARDs (csDMARDs)	Targeted synthetic DMARDs (tsDMARDs)	Biological originator (boDMARDs)	Biosimilar (bsDMARDs)
Methotrexate (MTX)	Tofacitinib	TNF blockers	TNF blockers
Leflunomide (LEF)		- Adalimumab (HUMIRA)	- Etanercept (BENEPALI)
Sulfasalazine (SSZ)		- Certolizumab (CIMZIA)	- Infliximab (REMSIMA, INFLECTRA)
Hydroxychloroquine*		- Etanercept (ENBREL)	
		- Golimumab (SIMPONI)	
		- Infliximab (REMICADE)	
		Anti-IL6R	
		- Tocilizumab (ROACTEMRA)	
		LcT co-stimulation blocker	
		- Abatacept (ORENCIA)	
		Anti-CD20 (LcB targeting)	
		- Rituximab (MABTHERA)	
		IL-1Ra	
		- Anakinra (KINERET)†	

TNF=tumour necrosis factor; IL6R=Interleukine 6 Receptor; LcT= T lymphocyte; CD20, cluster of differentiation 20; LcB=B lymphocyte; IL-1Ra=interleukine 1 antagonist;

* Usually used in combination with MTX. † Anakinra is exceptionally used for the treatment of rheumatoid arthritis, because it is less effective and of more constraining use (see below).

1.2 Conventional synthetic DMARDs (csDMARDs)

The discovery of synthetic DMARDs as effective antirheumatic drugs has traditionally been based on empirical data, in contrast with recently introduced biological DMARD agents, which were developed from bench to bedside. The synthetic DMARDs most commonly used include methotrexate (MTX), sulfasalazine (SSZ), leflunomide (Table 3). Hydroxychloroquine (HCQ) is usually used in combination with MTX, and rarely alone.

Older molecules (azathioprine (AZA), gold salts, minocycline, cyclosporine A or D-penicillamine) are now rarely used, either because they did not demonstrate the same level of efficacy – especially on structural damage – or because their risk/benefit ratio appears less interesting than the previous one.

Glucocorticoids, although they may have a DMARD effect, have a specific positioning as bridging therapy, i.e., as short-term therapy aiming to rapidly control disease activity before getting the full efficacy of DMARDs. This will be discussed in In-Depth Discussion 2 (www.eular-onlinecourse.org).

Conventional synthetic DMARDs are therefore considered the first step in the pharmacological treatment of RA and should be started in all patients as soon as possible after diagnosis, to reduce disease activity, control joint damage and prevent disability (Smolen et al, 2010; Smolen et al, 2014*, Smolen et al, 2016*). This concept will be detailed in the strategies section and in Appendix 1.

1.2.1 Methotrexate

MTX is the anchor drug in the treatment of RA, both in monotherapy and combination therapy, due to a favourable efficacy/toxicity ratio. It is effective over long periods of time and it has a better toxicity profile and a slightly faster onset of action than other synthetic DMARDs. It was one of the first conventional DMARDs with proven efficacy on radiographic progression.

➡ Mechanism of action

MTX resembles folic acid and is a competitive inhibitor of folate-dependent enzymes, such as dihydrofolate reductase (DHFR). These enzymes are involved in the pyrimidine (DNA) synthesis and the de novo purine synthesis of DNA and RNA. DHFR inhibition by MTX leads to depletion of tetrahydrofolates that are essential for DNA, RNA and protein synthesis (figure 5).

Figure 5: MTX mechanism of action. After being taken into the cell both methotrexate (MTX) and polyglutamated forms of MTX inhibit dihydrofolate reductase, an enzyme that catalyses the conversion of dihydrofolate into tetrahydrofolate, which is the active form of folic acid. Tetrahydrofolate is involved in many single-carbon transfer reactions, including the synthesis of pyrimidines. Inhibition of dihydrofolate reductase causes depletion of intracellular tetrahydrofolate, which has a cytotoxic effect, especially on rapidly dividing cells. MTX-polyglutamate (MTX-PG) also inhibits *de novo* purine synthesis and thymidylate synthase, which contribute to its cytotoxic effects. AICAR, amino imidazole-4-carboxamide ribonucleotide; AMP, adenosine monophosphate; ATIC, AICAR transformylase; DHF, dihydrofolate; DHFR, dihydrofolate reductase; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; IMP, inosine monophosphate; PG, polyglutamate; THF, tetrahydrofolate; TYMS, thymidylate synthetase.

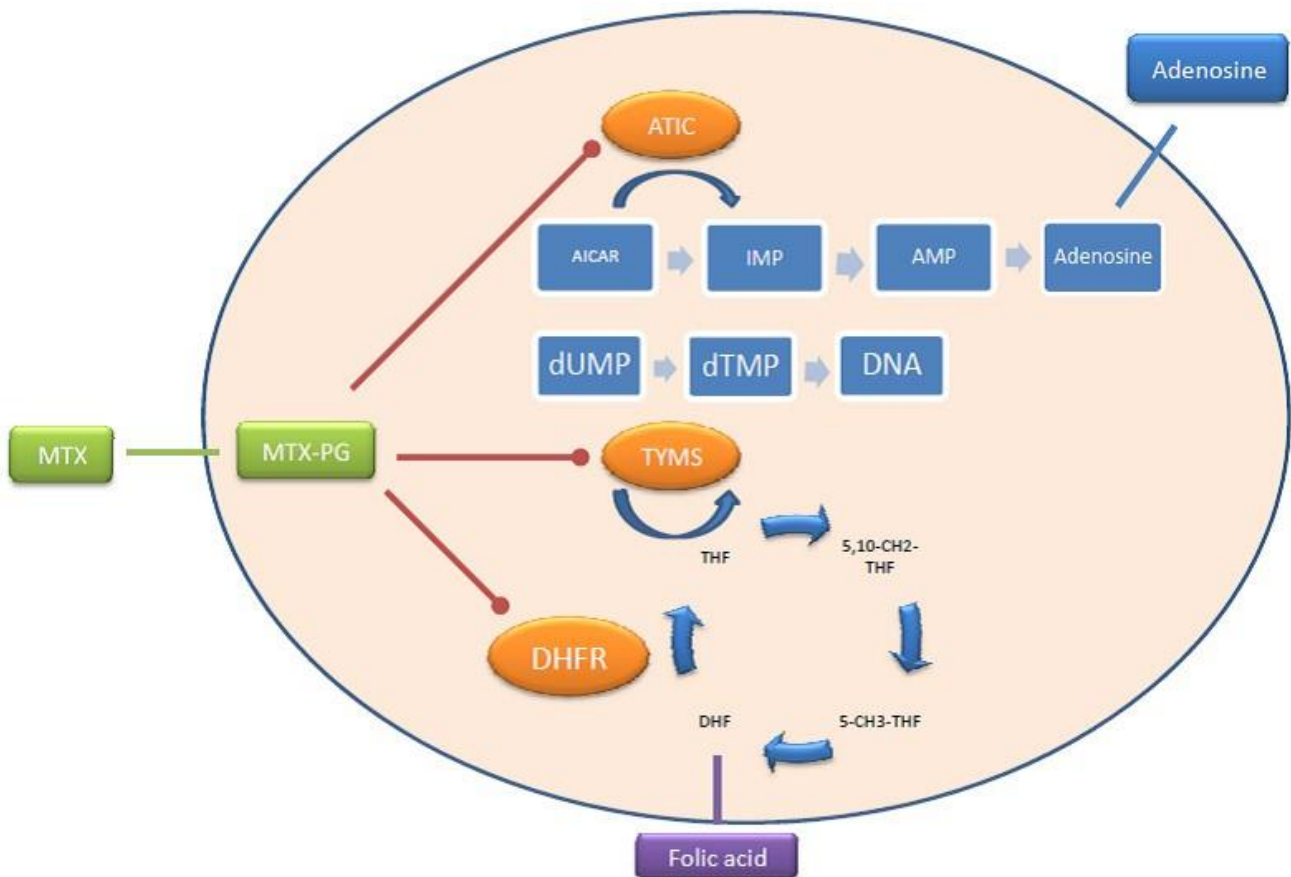

Table 3.A: main conventional synthetic DMARDs: mechanism of action, contraindications, precaution of use and main adverse effects.

	Methotrexate	Leflunomide	Sulfasalazine	Anti-malarial*
Mechanism of action	Reversible competitive inhibitor of DHFR (Folic acid analogue)	Isoxazole derivative (inhibits de novo pyrimidine synthesis)	5-aminosalicylic acid derivative, metabolised to sulfapyridine (active drug) and 5-ASA	4-aminoquinoline derivatives
Contraindications	<ul style="list-style-type: none"> - Pregnancy (teratogenic) - Concomitant use of trimethoprim-sulfamethoxazole (bone marrow suppression) - Severe chronic kidney failure - HIV or severe chronic infection - Anaemia, thrombocytopenia 	<ul style="list-style-type: none"> - Pregnancy (teratogenic) - Breast-feeding 	<ul style="list-style-type: none"> - G6PD deficiency - Hypersensitivity to sulfamides or salicylic acid - Porphyria 	<ul style="list-style-type: none"> - Retinopathy - Hypersensitivity to 4-aminoquinoline derivatives
Precaution of use	<ul style="list-style-type: none"> - Chronic liver disease† - Chronic pulmonary disease‡ 	<ul style="list-style-type: none"> - Hypertension - Renal and hepatic diseases 	<ul style="list-style-type: none"> - Haematologic problems - Renal and hepatic diseases 	<ul style="list-style-type: none"> - Impaired renal or hepatic function (↑risk of retinopathy)
Main adverse effects	<ul style="list-style-type: none"> - Mild GI complaint, nausea, vomiting, - Elevated transaminases (tolerated if <3N) - Hypersensitivity pneumoniaφ - Haematologic toxicity (leukopenia, thrombocytopenia, megaloblastic anaemia, pancytopenia) - Skin rash, hair loss - Subcutaneous nodules - Infections (viruses, opportunistic) 	<ul style="list-style-type: none"> - Diarrhoea - Hypertension - Hair loss - Elevated transaminases, cytolytic hepatitis - Rare: pancytopenia, peripheral neuropathy, vasculitis, interstitial pneumopathia, cutaneous lupus 	<ul style="list-style-type: none"> - GI complaints (nausea, pain) - Headaches, dizziness - Skin rash, - Lyell syndrome, DRESS syndrome - Leukopenia, agranulocytosis, thrombocytopenia - Haemolysis (G6PD deficiency) - Reversible oligospermia - Rare: cytolytic hepatitis, eosinophilic pneumonia or pulmonary fibrosis, ANA, anti-DNA Ab or drug induced lupus 	<ul style="list-style-type: none"> - Retinopathy - Anorexia, nausea, vomiting, GI complaints - Headaches, dizziness - Skin rash, pruritus - Skin pigmentation - Alopecia - Neuromyopathy - Leukopenia, thrombocytopenia, anaemia

DHFR, dihydrofolate reductase; MTX, methotrexate; GI, gastrointestinal; HIV, Human Immunodeficiency Virus; 5-ASA, 5-aminosalicylic acid; G6PD, glucose-6-phosphate dehydrogenase; ANA, antinuclear antibody; Ab, antibody; SSZ, salazopyrine; GFR, glomerular filtration rate; † The patient should be referred to a specialised hepatic consultation to ask for authorization; ‡ the patient should be referred to a specialised pulmonary consultation to ask for authorization; § requires to stop definitely the treatment

Table 3.B: modalities of prescription of the main conventional synthetic DMARDs.

	Methotrexate	Leflunomide	Sulfasalazine	Anti-malarial*
Mode of administration	Oral or SC	Oral	2g-3g/day in two divided doses	Hydroxychloroquine 2x200mg/day (≈6mg/kg/day) Chloroquine 2 100mg/day (≈3-4mg/kg/day)
Dose	≈ 10 to 25 mg/week** (3 mg/kg/week) Folic acid 5 to 10 mg/week, given 48 hours after MTX	If not well tolerate, can be decreased to 10 mg/day	(Gradual increase: 500mg a week)	Ideally in combination with other DMARD (no structural effect)
Mean half life	10 hours	15-18 days, but long persistence (enterohepatic circulation)	6-10 hours	40 days
Screening investigations	Please refer to table 4	<ul style="list-style-type: none"> Full past medical history and clinical examination to exclude a contraindication. Take into account the precautions of use (see table 3.A) CBC, liver enzymes, creatinine 		
Monitoring	CBC, liver enzymes, albuminemia, creatinine: Per week during the first 3 months, then/3 months	Avoid to use in patients with hypertension Blood pressure, CBC, liver enzymes, creatinine: Per 15 days during 6 months, then/2 months	Exclude G6PD deficiency CBC, liver enzymes, creatinine: Per month during the first 6 months, then space out	Ophthalmologic assessment at baseline (within the 1 st year of starting) - Ophthalmologic assessment at baseline, then annual after 5 years or earlier according to risk factors of retinopathy¶ - Electrocardiogram before and after treatment start; CBC and renal function - For some centres: HCQ serum levels (compliance check)
Mean time to be active/therapeutic response evaluation	6-8 weeks/3 months	6-8 weeks/3 months	3-4 months	2-4 months
Interruption before scheduled surgery†	- No need if scheduled orthopaedic surgery - Necessary to stop if septic surgery (15 days before)	- Not adequate (long half-life) - For some authors, wash out if high septic risk surgery	- Not systematic - If risk of interference with other drugs, hepatotoxicity or reduction of GFR, SSZ can be stopped 1-2 days before surgery.	Not necessary
Interruption before pregnancy‡	3 months	2 years or do a wash-out (cholestyramine 3x8g/day during 11 days)	Not necessary (but use with caution if breast feeding)	Can be continued throughout pregnancy Compatible with breast feeding

* Hydroxychloroquine and chloroquine; ** the same day of the week; ¶ Risk factors of retinopathy: long-term use (1% after 5-7 years or 1000 mg of cumulative dose), impaired renal or hepatic function, age >60 years, obesity, retinal or macular disease, cytochrome P450 gene polymorphisms or a prior history of antimalarial drug use. Assessment should include visual fields and SD OCT (spectral-domain optical coherence tomography), and multifocal electrinogram (mfERG) and/or fundus auto fluorescence. † Perioperative management of csDMARDs is detailed in In-Depth Discussion 3. ‡ Periconceptional management of cs DMARDs is detailed in Appendix 2.

The mechanisms by which MTX exerts its effects are complex and yet not fully known. Several mechanisms have been proposed: inhibition of T cell proliferation due to the effects of MTX on purine and pyrimidine metabolism, inhibition of transmethylation reactions required for the prevention of T cell cytotoxicity, interference with glutathione metabolism leading to alterations in recruitment of monocytes and other cells to the inflamed joint, and promotion of the release of the endogenous anti-inflammatory mediator adenosine (Cronstein et al. 2005). The probable anti-inflammatory effect of MTX is suggested clinically by the rapid clinical response to treatment as well as the equally rapid flare of disease once it is stopped.

➡ Metabolism

The bioavailability varies according to the administration form. The bioavailability of doses superior to 15mg/week administered orally is highly variable, and represents on average two-thirds of that of subcutaneous (SC) or intramuscular (IM) administration (Jundt et al. 1993; Schiff et al. 2014) (Figure 6). This conducted authors to recommend oral administration with 2 MTX intakes on the same day for patients receiving doses > 15 mg/week.

Figure 6: Bioavailability of MTX after oral or parenteral administration. There is a consistently greater bioavailability of subcutaneous (SC) MTX compared with oral MTX. Mean oral MTX exposure plateaus at doses ≥ 15 mg/week. AUC, area under the concentration versus time curve; MTX, methotrexate; SC, subcutaneous; SEM, standard error of the mean (adapted from Schiff et al. 2014 with permission).

After absorption, 50–70% is bound to plasma proteins, mainly albumin. In case of hypoalbuminemia, quite frequent in severe RA, plasmatic free-MTX levels can be elevated. Serum and synovial fluid concentrations of MTX are approximately equal. MTX is principally (80–90%) excreted by the kidneys: hence, in case of kidney failure, MTX excretion is decreased and thus toxicity increased.

➡ Efficacy in RA

Many randomised controlled trials versus placebo or versus other DMARDs (leflunomide, azathioprine, gold, cyclosporine, penicillamine)) have demonstrated MTX clinical and structural efficacy (*Gaujoux-Viala et al. 2013). The percentage of responders to MTX is high, between 50 and 60%. The onset of action is about 4 to 8 weeks, with a maximal clinical efficacy usually obtained during the 6 first months. MTX also improves the quality of life evaluated through functional indexes, and could allow steroids interruption in 12 to 33 % of patients (Bannwarth 1994). MTX is considered as the optimal 1st line agent in RA and is used as an anchor therapy on which other csDMARDs, tsDMARDs or bDMARDs can be added in case of inadequate response.

➡ MTX prescription in practice

The strategy of prescription has been adopted by several countries as a result of the 3E (Evidence, Expertise, Exchange) initiative (Visser et al. 2008). The clinical, biological and imaging screening tests are detailed in table 4.

MTX can be administered orally or parenterally (subcutaneously or intramuscularly) at an optimal dose of 0.3 mg/kg/week. When high doses are used, splitting the dose can increase bioavailability (Hoekstra et al, 2006). Although the oral route is used most frequently, the parenteral route may be preferred in patients with inadequate clinical response or gastrointestinal intolerance. Furthermore, as seen previously (figure 6), for doses ≥ 15 mg/day, the biodisponibility is better with parenteral administration. Hence, several authors have compared the efficacy and safety of SC versus oral MTX. Initial treatment with SC was associated with lower rates of treatment changes, no difference in toxicity, and some clinical improvements (lower DAS-28 or better ACR20 and ACR70 responses) in disease control versus oral MTX over the first year in patients with early RA (Braun et al. 2008; Hazlewood et al. 2016). Lower doses are recommended in elderly people or in case of renal insufficiency. To ensure compliance and avoid administration errors, it is recommended to prescribe MTX on a specific weekday, which should be noted on the prescription form. The time of onset of action of MTX ranges from 2 to 6 weeks. Regular biologic monitoring is recommended: hemogram, serum creatinin, liver function tests and albuminemia every 1–3 months (Table 3).

MTX should be combined with folic acid to reduce gastrointestinal side effects (26% relative risk reduction) and the incidence of adverse events due to transaminase elevations (77% relative risk reduction), without loss of efficacy. In a literature systematic review a trend towards a reduction in mucosal side effects was reported,

but no conclusions could be drawn about haematological outcomes owing to poor reporting (Shea et al, 2013). Folic acid given at a dose of 5 to 10 mg/week is recommended usually 24–48 h after MTX to avoid counteractions. Higher doses of folic acid can be used in parallel with increases in MTX, but in the latter case, folic acid should not be prescribed within 24 h of MTX intake. Folinic acid (reduced folate), the form of the vitamin found before the metabolic reduction to tetrahydrofolate by dihydrofolate reductase, at 1 mg/day may be more potent than folic acid to combat acute MTX toxicity.

Table 4: Clinical, laboratory and imaging screening before starting methotrexate (MTX) and the general approach to the patient with rheumatoid arthritis

Clinical	<ul style="list-style-type: none"> ▪ Patient education: oral and written information ▪ Assess risk factors for toxicity: alcohol intake, hepatotoxic drugs, obesity, NASH... ▪ Assess contra-indications: <ul style="list-style-type: none"> ○ Absolute: pregnancy, haematologic disease (hypoplasia, thrombocytopenia, anaemia), chronic kidney or liver disease, alcoholism, chronic infectious disease, AIDS ○ Relative (require specialised assessment for authorization): chronic pulmonary disease, viral B or C hepatitis, diabetes, obesity ▪ Check compliance with vaccination plan. Vaccination according to recommendations*
Laboratory	<ul style="list-style-type: none"> ▪ Complete blood count, transaminases and liver function, creatinin, albuminemia, fasting glucose, lipid profile ▪ Serology for HIV, HBV, HBC ▪ Serum protein electrophoresis ▪ Pregnancy test (for women)

NASH, non-alcoholic steatohepatitis; CBC, complete blood count; AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; HBV, hepatitis B virus; HCV, hepatitis virus.

**For the vaccination plan and recommendations, please refer to the corresponding section of this course in Appendix 3*

➡ Adverse events

Adverse reactions to MTX are frequent and occur in more than half of patients. Some patients can develop several clinical or biological side effects. However, these adverse reactions tend to be minor and can often be managed without stopping the drug. The potentially serious side effects are listed in table 5, and the management of daily problems described in table 6. Predisposing factors for toxicity are high dose, long exposure, advanced age, renal insufficiency, hypoalbuminaemia, viral or alcoholic hepatitis and concomitant use of other antifolate treatments.

- o Hepatic adverse effects

Although MTX has a documented hepatotoxicity at high doses (especially those used in cancerology), MTX-induced liver fibrosis is very rare at low doses used in Rheumatology (Walker, et al. 1993). Thus, liver biopsies are not routinely needed, and regular monitoring of liver enzymes is sufficient. Risk factors for drug-induced fibrosis include: age > 60 at first prescription, renal failure, long duration of treatment, viral hepatitis, alcoholism, fatty liver.

Transaminase elevation is frequent (12 to 48 %), and dependent on the dose. An increase up to 2 fold the upper limit of normal is tolerated. When alanine aminotransferase and/or aspartate amino transferase (ALT/AST) increase to more than three times the upper limit of normal, it is recommended that MTX is stopped, but introduction later at a lower dose can be considered. If transaminases are persistently high despite interruption of MTX, other causes should be considered such as viral hepatitis, hepatotoxic drugs, hypoalbuminemia, fatty liver, alcohol intake, and appropriate diagnostic procedures should be performed, including a hepatological assessment (and a liver biopsy if needed). In case of pre-existing B or C hepatitis prior to MTX introduction, a hepatological assessment is essential, to consider viral activity and the benefit/risk ratio of prescribing the drug.

- o Hypersensitivity pneumonia

Hypersensitivity pneumonia is a rare – but serious and potentially fatal- adverse event that presents as an acute syndrome, usually early in the course of MTX treatment (<0.5% cases within 3 years of follow-up in a review by Salliot and van der Heijde, 2009). Risk factors that contribute to its occurrence are probably idiosyncratic as for other hypersensitivity reactions. Pre-existing lung disease is reported to be the most consistent risk factor, but it has not been related to MTX dose. There is no consensus about the data for age, disease duration, smoking and diabetes. Cough, dyspnoea and fever are the most common symptoms. Chest X-rays and scannography show an interstitial syndrome. The differential diagnosis includes severe infectious pneumonia, particularly *Pneumocystis jirovici* pneumonia. A bronchoscopy for bronchoalveolar lavage (BAL) is essential for diagnosis (the BAL will show an alveolitis rich in TCD4 lymphocytes). When the diagnosis of hypersensitivity pneumonia is suspected, MTX should be stopped, and if confirmed, the patient should be treated by high doses of methylprednisolone and MTX should be definitively contra indicated. The fatality rate has been reported to be as high as 17% and the reaction tends to occur early in the course of treatment (50% of cases in the first 32 weeks). Progression to fibrosis is rare. Hence, the patient and his general practitioner should be systematically informed of this risk prior to MTX introduction. Furthermore, a chest X-ray is systematic in the screening before treatment, and a pulmonary assessment is essential in case of pre-existing chronic pulmonary disease.

Table 5: Potential serious side effects of low dose MTX, with clinical expression and predisposing factors

Toxicity	Clinical expression	Predisposing factors
Hepatopathy	<ul style="list-style-type: none"> ▪ ↑ transaminases (low progression) 	<ul style="list-style-type: none"> ▪ Pre-existing B or C hepatitis ▪ Alcoholism ▪ Obesity, NASH ▪ Diabetes ▪ Age > 60 years-old ▪ Renal or cardiac failure

* NSAIDS, Non-Steroidal Anti-Inflammatory Drugs; **CBC, complete blood count. † Periconceptional management of MTX is detailed in Appendix 2.

o Haematological toxicity

Haematological toxicity (leukopenia, thrombocytopenia, megaloblastic anaemia, pancytopenia) occurs in about 3% of patients treated with MTX. The frequency is increase in patients > 65 and in case of chronic kidney failure (which increases the MTX concentration in serum). Although concomitant use of NSAIDs seems to be safe, anti-inflammatory doses of aspirin (> 1g/j) should be avoided, especially in case of chronic kidney disease, because it decreases the tubular excretion of the drug. Cases of bone marrow suppression with concomitant use of trimethoprim-sulfamethoxazole have also been reported, and this antibiotic should thus be avoided in case of MTX prescription.

- o Infections

Their frequency seems higher in MTX-treated patients, although it is not known with exactitude. They might be viral (especially herpes zoster, cytomegalovirus), bacterial community or opportunistic (*Pneumocystis carinii*, *Aspergillus*, *Cryptococcus* or *Nocardia*). In case of scheduled orthopaedic surgery, low-dose MTX can be continued during the elective perioperative period without an increased risk of complications and this minimises postoperative RA flares (Pieringer et al, 2007; Loza et al, 2009; Harle et al, 2010). However, it is essential to stop it at least 15 days before the intervention in case of septic surgery (Table 3).

- o Malignancies and lymphoma

The link between MTX and cancer has not been demonstrated. The link between MTX and lymphoma is complex. RA patients, independently of MTX use, are at higher risk of developing a lymphoma, especially a non-Hodgkin type. However, B-lymphoma have been reported in RA patients treated with MTX (Mariette et al, 2002). Epstein-Barr virus seems to play a role, as the serology is positive in 50 % of the patients. These lymphoma are sometimes regressive after MTX discontinuation.

- o Other side effects

Rash

Dermal toxicity include rash, hair loss (often regressive when MTX is stopped or folinic acid increased), localised skin reaction (pruritus, red patch, haematoma) with subcutaneous administration. Subcutaneous nodules related to RA may worsen during MTX treatment, or appear under treatment if not existing previously. These nodules can sometimes be located inside the lungs.

Mild gastrointestinal complaints

They are very frequent (20 to 60% of patients), and even more frequent when MTX is used orally and at high doses. They include nausea, vomiting, anorexia, and diarrhoea or stomach ache. To minimise these non-serious gastrointestinal side effects switching from oral to parental (preferentially subcutaneous). MTX might be helpful, based on studies that demonstrate better tolerability with intramuscular formulations. Splitting the dose, although commonly performed, is mainly supported by expert opinion.

Teratogenicity

MTX is teratogenic, and should not be given to pregnant or breast-giving women. More details about the periconceptional management of MTX can be found in Appendix 2.

1.2.2 Leflunomide

➡ Mechanism of action

Leflunomide is an isoxazole derivative and a prodrug whose active metabolite is malononitrilamide A77 1726. It inhibits de novo pyrimidine synthesis, resulting in diverse antiproliferative and anti-inflammatory effects such as suppression of TNF-induced cellular responses and inhibition of matrix metalloproteinases and osteoclasts.

➡ Metabolism

The half-life of the active compound is 15 days. Leflunomide and its active metabolite are extensively protein bound and undergo further metabolism before excretion, which at the same time hepatic and renal. Leflunomide persistence in the organism can reach two years, because the molecule is reabsorbed through an enterohepatic cycle. The absorption can be interrupted through the use of cholestyramine or activated charcoal.

➡ Efficacy in RA

Leflunomide has demonstrated to be as efficacious and safe as MTX, and is currently the best alternative in this indication. Leflunomide monotherapy is not inferior to MTX in controlling disease manifestations in both early and established RA and in slowing radiographic damage (Cohen et al. 2001; Sharp et al. 2000; Smolen et al. 2004). Combination therapy of leflunomide and TNFi might also be as effective as its combination with MTX, but adequate randomised controlled trials have not been undertaken. Interpretation is based on small cohort studies and is not completely consensual (Finckh et al, 2009; De Stefano et al, 2010; Benucci et al, 2011). The two-year therapeutic maintenance level of leflunomide is not significantly different from MTX (\approx 85% versus 79 %, Cohen et al. 2001).

➡ Leflunomide prescription in practice

The screening investigations are detailed in table 3. Because of its slow onset of action (approximately 6–8 weeks) a loading regimen of 100 mg daily for 3 days was initially advocated to rapidly achieve clinically active serum concentrations. Most clinicians, however, do not now use this regimen owing to toxicity, and results from the LEADER study confirmed that in DMARD-naïve patients, a loading dose does not increase efficacy at 3 months, in comparison with a fixed regimen of 20 mg/day, and is associated with a higher rate of adverse events (Cutolo et al, 2010). The dose can be decreased to 10 mg/day but, owing to the long half-life of the active metabolite, a prolonged period may be required before plasma levels decline after dosage reduction.

➡ Side effects and contraindications

Leflunomide may increase the risk of foetal death and have teratogenic effects and should only be started if pregnancy is excluded and is not planned for the near future. Because of a lack of data, it is safer not to use leflunomide in lactating women (Götestam Skorpen et al. 2016). In view of its long half-life, a course of cholestyramine (3×8 g daily for 11 days) can be given to facilitate clearance of the active compound. Without washout, elimination of leflunomide may take 2 years but even with washout, pregnancy should be avoided within 6 months of stopping the drug. Women taking leflunomide who wish to conceive must discontinue the drug and undergo cholestyramine washout before attempting conception. Other contraindications to the use of leflunomide include liver disease, severe renal impairment, severe immunodeficiency and rifampicin therapy. Adequate monitoring of side effects, including raised liver enzymes, diarrhoea, alopecia, high blood pressure, rash and leukopenia, is required (Table 3). Cases of leflunomide-induced pneumonitis and reversible axonal sensory motor peripheral neuropathy have also been described.

1.2.3 Sulfasalazine

➡ Mechanism of action and metabolism

SSZ is a 5-aminosalicylic acid derivative which is metabolised via the colonic intestinal flora to sulfapyridine and 5-aminosalicylic acid (5-ASA) and, after absorption, it is metabolised further. Sulfapyridine is the active moiety in RA and rheumatic diseases, although its mechanism of action has not been identified. It is mainly excreted in the urine, either as unchanged drug or as its metabolites, with a relatively short half-life (<10 h). 5-ASA has an action on the digestive mucosa, by decreasing IgAs, explaining its role in inflammatory bowel diseases.

➡ Efficacy in RA

In randomised double-blind placebo controlled trials, SSZ was associated with statistically significant benefits for various measures of disease activity according to the results of individual trials and/or meta-analysis (Weinblatt et al. 1999). It had similar efficacy to that of various other synthetic DMARDs in several randomised double-blind comparative trials. Although SSZ has a structural effect similar to leflunomide (Scott et al. 2001), and in spite of the absence of clear clinical differences in the rare head-to-head controlled studies of SSZ versus MTX, SSZ is often considered to be less efficient than MTX. This might also be related to limited compliance to high-dose SSZ owing to the large number of daily pills (four to six) that has to be taken continuously.

➡ SSZ prescription in practice

SSZ is prescribed at doses of 2–3 g/day in two divided doses. A gradual increase in dose (500 mg a week, for instance) should be performed to minimise potential toxicity when beginning SSZ treatment. The dose should

be adapted in case of renal or liver insufficiency. Hypersensitivity to sulfa drugs or salicylates or glucose-6-phosphate dehydrogenase deficiency should be assessed, and the drug should not be given if present. The screening investigations and monitoring are detailed in table 3.

➡ Side effects and contraindications

SSZ was generally well tolerated in clinical trials, although approximately 20–25% of patients withdrew because of intolerable side effects—two-thirds of which result from gastrointestinal symptoms or central nervous system toxicity (headache, dizziness) and about 4–5% are due to rash. Most adverse effects occur in the first months of treatment (table 3). Myelopoiesis inhibition can also occur at any time and periodic laboratory screening is therefore recommended, particularly in patients with impaired renal or hepatic function or blood dyscrasia. Patients should be informed of the risk of severe drug reaction: bullous dermatosis such as Lyell syndrome or DRESS (drug reaction with eosinophilia and skin syndrome) characterised by fever, rash and markedly abnormal liver function tests may be induced by SSZ, resembling a viral illness, which should lead to prompt discontinuation of the drug. Patients with known hypersensitivity to sulfa drugs or salicylates and those with glucose-6-phosphate dehydrogenase deficiency (risk of haemolysis) should not be given SSZ. Some patients receiving SSZ may develop orange-coloured urine, tears or skin. It is one of the few DMARDs (together with HCQ and low-dose glucocorticoids) that are relatively safe in pregnancy, although it should be used with caution in women who are breast-feeding. In men, SSZ may cause reversible oligospermia.

1.2.4 Antimalarial agents

➡ Mechanism of action and metabolism

The antimalarial agents - mainly hydroxychloroquine (HCQ), because chloroquine (CQ) is not used in common practice for RA treatment- are 4-aminoquinoline derivatives. Their mechanism of action is imperfectly known. They concentrate inside cells within acidic cytoplasmic vesicles, resulting in changes in acidity, and interfere with the processing of auto antigenic peptides. It was shown that antimalarial agents can interact with nucleic acids and inhibit endosomal Toll-like receptor activation, suggesting a potential mechanism to modulate activation of the innate immune system (Kuznik et al, 2011). Furthermore, antimalarial agents exert in vitro protective effects against the disruption of annexin A5 by antiphospholipid antibodies, improve lipid profile and reduce the risk of diabetes in patients with RA (Bili et al, 2011; Morris et al, 2011; Solomon et al, 2011).

HCQ is absorbed from the gastrointestinal tract and have extended serum half-lives due to tissue depot effects. It takes 2–4 months for antimalarial agents to become effective. Excretion of HCQ is mainly by renal clearance and its dose should be reduced in patients with renal insufficiency.

➡ Antimalarial drug prescription in practice

HCQ did not demonstrate significant efficacy in joint damage prevention and is therefore recommended in combination with MTX, as it may contribute to a higher peak and area under the curve concentrations of MTX in blood, or in association with other DMARDs (Smolen et al, 2010; Smolen et al, 2014*). The doses recommended are detailed in table 3.

Monitoring should include proper eye management. Recent recommendations of the American College of Ophthalmology propose a baseline assessment, within the first year of starting the drug, then at 5 years and annually afterwards to exclude maculopathy (Marmor et al. 2016). This assessment should include: fundus examination, visual fields, multifocal electrinoqram (mfERG) and/or fundus auto fluorescence, plus and spectral-domain optical coherence tomography (SD OCT) if maculopathy is present. At recommended doses, the risk of toxicity up to 5 years is under 1%.

Many centres also regularly control serum levels of HCQ: these measures could help to adapt the doses and thus to limit retinal toxicity, but are especially useful to check out patient compliance, as the serum elimination is long. The therapeutic levels for HCQ are commonly estimated to be higher than 500-1000 ng/mL.

➡ Adverse effects

Antimalarial drugs are generally well tolerated and serious adverse events are rare. The most feared adverse event is retinopathy, which is less common with HCQ than with CQ, and occurs only infrequently with low doses (HCQ < 5 to 6.5 mg/kg/day or CQ 2.3 to 3 mg/kg/day) (Marmor et al. 2016). The risk of retinal toxicity increases with long-term use (1% after 5–7 years or 1000 mg of cumulative dose), impaired renal or hepatic function, age >60 years, obesity, tamoxifen use, retinal and macular disease, genetic polymorphisms in the cytochrome P450 gene, or a prior history of antimalarial drug use (Marmor et al. 2016). HCQ and CQ retinopathy are not reversible, and cellular damage may progress even after the drugs are stopped. When retinopathy is not recognized until a bull's eye appears, the disease can progress for years, often with foveal thinning and an eventual loss of visual acuity. However, when retinopathy is recognized early, before retinal pigment epithelium damage, there is only limited progression after discontinuing the medication and the fovea will not be involved. Thus, screening may not “prevent” damage, but if conducted properly it enables the detection of toxicity before vision is significantly affected (Marmor et al. 2016). Headaches, dizziness, rash, pruritus, mild gastrointestinal complaints (anorexia, nausea, vomiting, abdominal cramps and diarrhoea) sometimes require its discontinuation, but no routine laboratory monitoring is required. Skin pigmentation and alopecia can occur. Neuromyopathy, haematological side effects (leukopenia, thrombocytopenia, anaemia) atrioventricular block due to antimalarial drugs (less common with HCQ) are rare complications.

1.2.5 Glucocorticoids

Although glucocorticoids do have a structural effect and can thus be considered as DMARDs (Kirwan et al, 2007), they also have a lot of side effects which might reduce their chronic use. Hence, most authors nowadays consider that their prescription should be, when possible, limited to “bridging therapy” in the initial treatment strategy, in combination with one or more csDMARDs, for up to 6 months, but should be tapered as rapidly as clinically feasible (Smolen et al. 2013). In practice, they can be useful to manage disease flares. These concepts and the modalities of prescription and monitoring will be detailed in In-Depth Discussion 2 (www.eular-onlinecourse.org).

1.2.6 Other DMARDs

Gold salts are the oldest group of synthetic DMARDs used in the treatment of RA, yet their mode of action remains poorly understood. Gold affects macrophage and B cell function and can modify matrix metalloproteinase (collagenase) production and antibody production. Some gold preparations can only be administered by intramuscular injection (gold sodium thiomalate and gold sodium thioglucose), starting at 10 mg/week followed by weekly dose increments up to 50 mg/week. Noticeable clinical effects are usually not achieved until after 4–6 months of treatment, making its onset of action the longest of all the DMARDs. If there is no response after a cumulative dose of 1 g has been given, gold treatment should be discontinued. If there is a favourable response, however, treatment can be tapered over a period of several months until an effective monthly maintenance dose has been found. The oral version (auronofin) is usually started at 6 mg/day in two split doses and then increased to 9 mg/day after 3 months. Injectable gold is more effective than oral gold, especially on progression of joint damage. Gold is generally well tolerated but can lead to severe allergic reactions (skin rash), stomatitis, proteinuria, neuropathy, thrombocytopenia and potentially life-threatening bone marrow aplasia requiring prompt discontinuation. Although rarely used nowadays because of the frequency of adverse effects, gold as monotherapy or in combination with prednisone or MTX remains an alternative for patients with refractory disease. AZA, cyclophosphamide, cyclosporine, D-penicillamine, tacrolimus and tetracycline derivatives (minocycline, doxycycline) are sometimes used in the treatment of RA. AZA and cyclophosphamide use is declining because of their side effects (myelosuppression, increased risk of infection and malignancies with long-term use, and hepatotoxicity). Cyclosporine is an effective DMARD, especially in combination with MTX, but its toxicities (hypertrichosis, tremor, gum hyperplasia, hypertension and dose-related loss of renal function), though reversible in most cases, have prevented its widespread use. Tetracycline derivatives inhibit metalloproteinase activity involved in joint destruction and are sometimes used as adjunctive treatment early in the disease (Gaujoux-Viala et al, 2010 and 2013).

Given the wide array of more effective and safer DMARDs and with the introduction of effective biological agents, these DMARDs are mainly reserved for patients with refractory RA, intolerant to previously described DMARDs and biological agents.

1.2.7 Combinations of cs DMARDs

This point will be detailed further in the strategy section.

Summary points: conventional synthetic (cs) DMARDs

- ➔ csDMARDs should be started in every patient upon diagnosis.
- ➔ Methotrexate (MTX) is the preferred first-line DMARD owing to its good efficacy/safety ratio.
- ➔ Leflunomide or SSZ should be considered as an alternative when MTX fails or is not tolerated.
- ➔ Antimalarial drugs are weak DMARDs when used as monotherapy, but they can be used in association with other DMARDs and may have additional benefits in patients with RA and a high risk of cardiovascular disease.
- ➔ Glucocorticoids in low to moderate doses have an important role as bridging treatment in early disease or during flares, in addition to csDMARDs, due to their high efficacy and rapid onset of action. This concept will be detailed in In-Depth Discussion 2.
- ➔ In DMARD-naïve patients, csDMARD monotherapy with or without glucocorticoids should be preferred to csDMARD combination therapy (2016 EULAR recommendations update, please see the strategies section below).

1.3 Biological DMARDs (bDMARDs)

Numerous biological agents that target inflammatory cytokines, cytokine receptors or cells within the synovium and immune system have been developed during the last 20 years.

Owing to the broad information and scientific literature on this topic, the text given in *italic* is only informative for the student and no assessment questions will be asked on it. Further information can be found through small clinical vignettes of the main randomised controlled trials in Appendix 1.

1.3.1 Targeting cytokines or cytokine receptors using biological agents

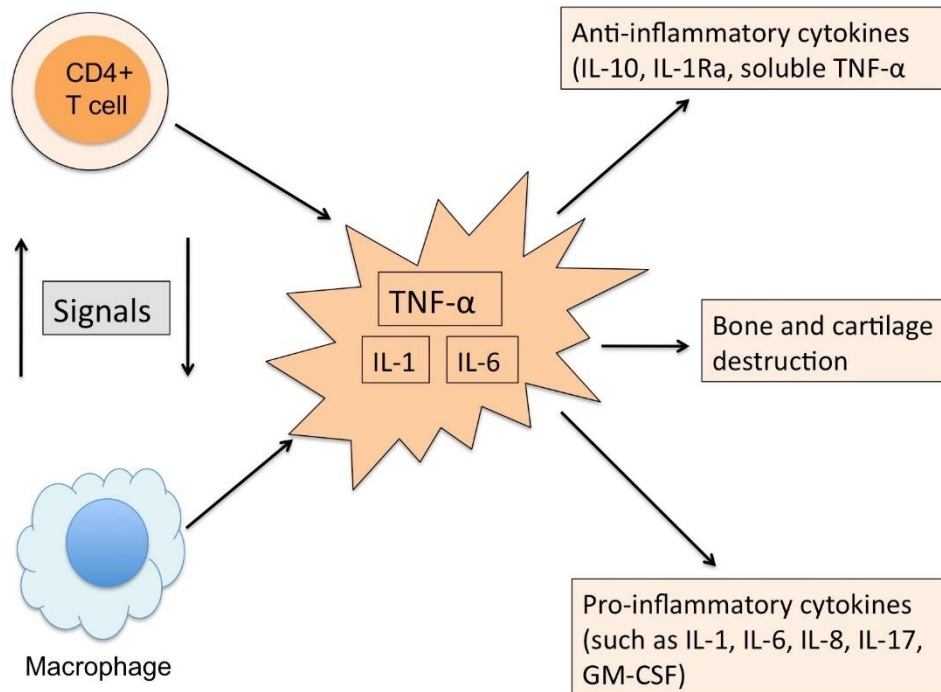

A broad range of cytokine pathways are activated in RA synovitis, especially pro-inflammatory cytokines such as TNF α (Tumour Necrosis Factor α) and interleukine (IL)-1 and IL-6 (McInnes and Schett, 2007*) (Figure 7).

More details on RA pathophysiology can be found in the dedicated course (www.eular-onlinecourse.org).

Cytokines are peptides that exist in families of related molecules. They function by binding to a specific receptor on a target cell and thereby facilitate communication within the immune system between cells that may be required to operate together but which may be situated some distance apart. For instance, the biological effect of TNF α and the activation of the target cell require the binding of the cytokine with the membrane receptors p55 or p75. These membrane receptors also exist in a soluble circulating form, and are

currently considered as natural inhibitors of TNF, because they can decrease its bioavailability while binding it (Singh et al. 2009).

Figure 7: Simplified representation of the cytokine cascade in the pathophysiology of rheumatoid arthritis.

TNF-α mediates diverse activities in RA, including local activation of synovial leucocytes, endothelial cells, platelets, synovial fibroblasts, chondrocytes and osteoclasts. It also mediates systemic effects, in part via driving IL-6 and hence acute phase responses, or IL-1 and joint destruction. TNFα acts as a critical checkpoint cytokine in the inflammatory cascade and, thus agents that block its activity have, in general, been associated with marked clinical improvement and prevention of joint destruction.

TNF-α, Tumour Necrosis Factor α; IL, interleukin; Ra, Receptor antagonist; GM-CSF, granulocyte macrophage colony stimulation factor.

Nomenclature

The advent of sophisticated molecular technology has allowed the generation of highly specific molecular antagonists to cytokines or cytokine receptors (Hueber et al, 2010).

These targeted treatments may be:

1. monoclonal antibodies, with usually as suffix “mab” (“ximab” for chimeric antibodies, “mumab” for fully human, “zumab” for humanised, e.g., infliximab, adalimumab, certolizumab, golimumab, tocilizumab),
2. native cytokine receptors coupled to the Fc component of human immunoglobulin, with suffix “cept” (e.g., etanercept)
3. recombinant antagonists that closely resemble the cytokine structure but deliver no signal when bound by receptor (e.g., anakinra) (figure 8).

Figure 8: schematic illustration of the different mechanisms of action of biological treatments. A. Monoclonal antibodies (Ab).

Monoclonal antibodies (Ab) can be murine, chimeric, humanised or fully human, according to the suffix used. Humanisation decreases the risk of immunisation, thus increasing tolerance and therapeutic maintenance. Monoclonal Ab can be directed against a cytokine (TNF α for infliximab and adalimumab, IL-17 for secukinumab), a receptor (IL6-R for tocilizumab) or the membrane of a cellular type (CD20 of B lymphocytes for rituximab). Muromonab is a monoclonal Ab directed against CD3 used in prevention of graft reject. Denosumab is an Ab directed against receptor activator of nuclear factor kappa-B ligand (RANKL) used in osteoporosis. Secukinumab is an Ab in development in RA, spondylarthritis and psoriasis, directed against IL17.

Figure 8: schematic illustration of the different mechanisms of action of biological treatment (continued). B. Fusion proteins.

Fusion proteins couple a receptor and an IgG Fc-fragment, and usually have the suffix –cept. Etanercept is a soluble receptor aiming at TNF α . Abatacept inhibits T cell co-stimulation.

Figure 8.C. Recombinant antagonists.

Recombinant antagonists closely resemble the cytokine structure but deliver no signal when bound by receptor. Anakinra is a recombinant form of the natural endogenous IL-1 receptor antagonist called IL-Ra.

1.3.2 TNF inhibitors in RA

Five TNF inhibitors (TNFi) are currently available for the treatment of RA (**table 7**).

1.3.2.1 Anti-TNF antibodies in RA

➡ Infliximab

Infliximab is a human murine chimeric antibody that defined the fundamental importance of TNF in the pathogenesis of RA by the landmark studies of Feldman and Maini in the early 1990s (Feldmann and Maini, 2001). It binds both soluble and membrane-bound forms of TNF.

Infliximab and low-dose MTX promote benefit at the American College of Rheumatology 20% (ACR 20) level in around 60% of recipients within 8–12 weeks, with fewer patients achieving ACR 50 and ACR 70 responses. *The pivotal phase III study (ATTRACT study) compared MTX/placebo with MTX/infliximab combinations (four dose regimens) in patients with established RA with an inadequate response to MTX therapy. MTX/infliximab recipients showed significantly greater improvement after 1 year than MTX/placebo recipients judged by higher ACR 20, ACR 50 and ACR 70 response rates and reduced progression of the Sharp score (Maini et al, 1999).* Several studies have replicated and extended these data and a robust dataset indicates that infliximab is a well-tolerated and efficacious treatment for established RA.

Three studies indicate that infliximab may exhibit better efficacy if used in earlier disease. *In the ASPIRE study, recruitment of patients with early RA led to higher response rates at each ACR category level as compared with*

the results previously obtained in established disease, and prevented erosive progression. Improved responses are particularly evident compared with placebo when those patients presenting with high CRP levels were considered as a subset (Smolen et al, 2006). Additionally, the BeSt study—in which a variety of strategic approaches to RA treatment were compared—showed that infliximab added to MTX at an early disease stage can lead to significant improvements in clinical disease activity and prevent erosive progression. More importantly, this strategy can induce remission in a proportion of patients, which is maintained when infliximab is stopped and, in a small number of patients, even after stopping all treatments (Goekoop-Ruiterman et al, 2007). The pathophysiological mechanism for such better results in early intervention is not yet clear. Interestingly, infliximab can induce the generation of regulatory T cell subsets, which may promote reinstitution of immune tolerance in the presence of synovitis, and this may contribute to better results when this drug is used early on in the course of the disease.

Infliximab should be given as an infusion over 2 h, which can be decreased to 1 h after the third infusion if well tolerated. Infliximab should be prescribed together with MTX (at least 10 mg/week) or an equivalent csDMARDs (higher efficacy and less development of anti-drug antibodies). The drug is given on weeks 0, 2 and 6 and then 8-weekly thereafter. The licensed dose for use in RA is 3 mg/kg, although, in some patients, higher doses and/or increased frequency of administration may be required (e.g., increase up to 5 mg/kg every 6 weeks), depending upon local healthcare provider recommendations or when response is lost, to overcome neutralising antibodies. Plasma concentrations of infliximab and the formation of human antichimeric antibodies (HACAs) are known to be good predictors of response to infliximab at the individual level. Secondary failure has also been shown to be dependent, at least in part, on HACA synthesis, which is increased when infliximab is used in monotherapy.

➡ Adalimumab

Adalimumab was the first human monoclonal antibody against TNF to be licensed for use in RA. Several randomised controlled datasets support the use of adalimumab in RA, and indicate that it is better than placebo in controlling signs and symptoms and in retarding progressive erosive disease. *Two pivotal studies deserve specific mention. The ARMADA study was a phase III study in established RA, in which adalimumab/MTX was shown to be better than placebo/MTX as measured by ACR responses and erosive progression (Weinblatt et al, 2003). Response rates were broadly similar to those seen with other TNF blocking agents, with about 69% of patients achieving ACR 20 response. This clinical response was globally maintained over 4 years of open follow-up, with a safety profile similar to that of the first 6 months. Reduction of glucocorticoid and/or MTX dosages did not adversely affect long-term efficacy. Adalimumab has also been tested in patients with early RA. The PREMIER study examined patients with RA of <3 years' duration and compared adalimumab/MTX with MTX alone and with adalimumab alone (Breedveld et al, 2006). The*

combination was significantly better than either agent used alone in the generation of ACR 50 improvements and also in retarding erosive progression

Adalimumab is given as a 40 mg subcutaneous (SC) injection every other week. It should be used in combination with MTX (at least 10 mg/week) or an equivalent csDMARD, which decreases immunogenicity and improves efficacy, but in patients intolerant to MTX it can be used as monotherapy and the dose increased to 40 mg every week, if necessary. However, for reasons of safety and cost, this dose increase is rarely used.

➡ Certolizumab

Certolizumab is a humanised antibody, in which the recombinant Fab' fragment that recognises TNF has been conjugated with a polyethylene glycol chain. The pegylation of the Fab' fragment increases its half-life and can also reduce its immunogenicity, without affecting the affinity and specificity of the antibody.

Certolizumab was found to be better than placebo in patients who were MTX incomplete responders in two phase III trials (RAPID 1 and RAPID 2) (Keystone et al, 2008; Smolen et al, 2009a). Either 400 mg (RAPID 1) or 200 mg or 400 mg (RAPID 2) of SC certolizumab plus MTX were given at weeks 0, 2 and 4, followed by 200 mg or 400 mg every 2 weeks, for a total of 52 weeks (RAPID 1) or 24 weeks (RAPID 2), in parallel with a regimen of placebo plus MTX. In both studies, at week 24, a significantly higher percentage of patients receiving certolizumab (57% up to 61%) achieved ACR 20 as compared with those in the placebo arm (13.6% and 8.7%), with no differences in efficacy between the 200 or 400 mg doses, at any time. Clinical benefits were noted 1 week after treatment, achieved their maximum at weeks 16–20 and were maintained through weeks 52 (RAPID 1) and 24 (RAPID 2). A greater inhibition of radiographic progression, as evaluated by the mean change in the modified Total Sharp Score, was also identified in the certolizumab-treated group at the end of the studies. Furthermore, in patients who were forced to withdraw at 16 weeks owing to lack of response at weeks 12 and 14, effects on radiographic scores at this early time were also demonstrated, indicating that certolizumab may reduce joint damage even when ACR 20 is not achieved. Similarly, 400 mg of certolizumab given monthly as monotherapy when DMARDs have failed (FAST4WARD), is clinically efficacious, although with lower rates of patients achieving ACR 20/50/70 as compared with those receiving regimens in association with MTX (Fleischmann et al, 2009).

Table 7: summary table of the five TNF inhibitors available.

	Infliximab	Etanercept	Adalimumab	Certolizumab pegol	Golimumab
Mode of action	Chimeric monoclonal Ab	IgG-Fc-receptor construct (fusion protein)	Human monoclonal Ab	Humanised monoclonal Ab (Fab' fragment conjugated with PEG chain)	Human IgG1 monoclonal Ab (specific for both circulating and membrane bound TNF)
Mode of administration	IV	SC	SC	SC	SC
Dose	3 (to 5) mg/kg W0-W2-W6, then /6 to 8 weeks Mandatory association to MTX or other DMARD (Prevention of ADA)	50mg/week	40 mg every 2weeks	Induction regimen of 400mg at 0, 2 and 4 W, then maintenance dose of 200 mg/2weeks	50 mg/month
Mean half life	≈ 10 days	≈ 3-4 days	≈ 15 days	≈ 10-15 days	≈ 12-15 days
Contraindications	<ul style="list-style-type: none"> Active and/or chronic infections. Past history of severe or bad/untreated infection (tuberculosis +++) Hypersensitivity to the active substance or to an excipient Demyelinating diseases and/or retro-orbital optic disease 			<ul style="list-style-type: none"> Neoplasia* or hemopathia < 5 years Congestive heart failure (NYHA class III/IV and ejection fraction ≤ 50 %) Pregnancy and/or breast feeding Live attenuated vaccines¶ 	
Pre-treatment screening	<ul style="list-style-type: none"> Clinical examination**: exclude infections, malignancy < 5 years, congestive heart failure Patient education Exclude pregnancy Check for compliance with vaccination plan. Vaccination according to recommendations¶ Laboratory tests for CBC, liver function, creatinine, fasting glucose and lipid profile 			<ul style="list-style-type: none"> Serology for HIV, HBV and HVC (for some countries only if risk factors) Serum protein electrophoresis Antinuclear antibodies, and if positive, anti-DNA antibodies Exclude active or latent tuberculosis and treat according to local guidelines Chest X-ray examination Oral hygiene/stomatology assessment (for some centres) 	
Biologic monitoring	CBC, liver enzymes, creatinine, CRP before each infusion	CBC, liver enzymes, creatinine, CRP every three months	CBC, liver enzymes, creatinine, CRP every three months	CBC, liver enzymes, creatinine, CRP every three months	CBC, liver enzymes, creatinine, CRP every three months
Therapeutic response evaluation	4 th infusion	3 months	3 months	3 months	3 months If weight > 100 kg, possibility to increase dose to 100mg/months, after evaluating benefits/risks ratio
Interruption before scheduled surgery required (medium-high septic risk) [†]	4-8 weeks	2-4 weeks	8-10 weeks	8-10 weeks	8-10 weeks

Ab, antibody; ADA, anti-drug antibody; Fab', fragment antigen-binding; W, week; MTX, methotrexate; DMARD, Disease-Modifying Anti-Rheumatic Drug; IV, intravenous; SC, subcutaneous; CBC, complete blood count; HIV, human immunodeficiency virus; HBV, hepatitis B virus; HCV, hepatitis C virus; NYHA, New York Heart

*Association; CRP, C-reactive protein. *Other than non-melanoma skin cancer that was removed completely with disease-free margins** Detailed clinical examination and pre-treatment screening, for TNFi and other bDMARDs can be downloaded in English version on www.cri-net.com; ¶ Detailed information and vaccination guidelines are given in Appendix 3. †Perioperative management of bDMARDs is detailed in In-Depth Discussion 3*

The safety profile of certolizumab was comparable to that seen with other anti-TNF therapies. From a pooled analysis of 4065 patient-years in randomised and open-label trials, the most common side effects were infections, with respiratory tract infections and tuberculosis being the most common serious infectious events. Pain at the site of injection was referred in 1.8% and injection site reactions occurred in 7.9% of patients (lower than with other subcutaneous biological drugs). Of interest, a prolonged activated partial thromboplastic time was seen in about 5% of patients in RAPID 2, which reflects an interference of polyethylene glycol with phospholipids used in commercial assays and does not seem to translate into any effect on coagulation in vivo (Fleischmann, 2010).

Certolizumab is approved for the treatment of moderate to severe RA by the Food and Drugs Administration (FDA) and by the European Medicines Agency (EMA) with an induction regimen of 400 mg at 0, 2 and 4 weeks, followed by a maintenance dose of 200 mg every other week, with subcutaneous administration in association with MTX

➡ Golimumab

Golimumab (Singh et al, 2010), a fully human IgG1 monoclonal antibody specific for both circulating and membrane-bound TNF, has been developed upon TNF immunisation of genetically modified mice (Zhou et al, 2007). Three pivotal randomised placebo-controlled clinical trials demonstrated the efficacy and safety of golimumab in MTX-naïve (GO-BEFORE), MTX inadequate responder (GO-FORWARD) and anti-TNF failure (GO-AFTER) patients with RA. The GO-BEFORE study, which included patients with <3 years' disease duration, did not detect significant differences in ACR 50 responses (primary end point) between the combination therapy groups of golimumab (50 or 100 mg) every 4 weeks plus MTX and MTX as monotherapy, but a difference would have been seen if the ACR 20 responses had been considered. A decrease in joint damage was shown at week 52 in the active treatment arm plus MTX in comparison with MTX monotherapy (Emery et al, 2009b). Using the same study design, GO-FORWARD showed significantly higher ACR 20 responses at week 14, in patients with active disease despite MTX therapy, treated with golimumab 50 and 100 mg, in combination with MTX (56%), compared with MTX and placebo (33%). The ACR 20 responses were detected as early as 4 weeks and in general increased until week 24 (Keystone et al, 2009). The follow-up analysis of the GO-FORWARD study, including the subgroup of patients who entered early escape at week 16 combined with those who crossed over from placebo to active treatment, showed that efficacy was sustained up to 52 weeks (Keystone et al, 2010).

In the GO-AFTER study, patients for whom TNFi had failed or been discontinued were assigned to one of three arms: placebo, golimumab 50 mg or golimumab 100 mg SC every 4 weeks, with concomitant DMARDs being allowed. A significantly greater proportion of patients in the golimumab combination groups (37%) achieved ACR 20 as compared with placebo (18%) (Smolen et al, 2009b). Both the GO-BEFORE and GO-FORWARD included a golimumab monotherapy arm and although 100 mg golimumab was associated with some clinical benefit, this was not better than with MTX alone. Similarly, there was no clear difference in the efficacy of the two golimumab doses, and golimumab 100 mg plus MTX was associated with higher rates of serious adverse events. Therefore 50 mg once a month in combination with MTX is the regimen approved both in the USA and Europe. The safety profile of golimumab is identical to that of other anti-TNF drugs.

1.3.2.2 TNF blocking agents in RA: soluble receptor

➡ Etanercept

Etanercept is a recombinant TNF receptor fused to a human Fc molecule creating a bivalent TNF binding agent. It has a shorter “on and off” binding rate to TNF than the antibodies noted above, which may account for its distinct pharmacodynamics and, perhaps also, mode of action.

Several randomised controlled double-blind trials provide the core evidence for its benefit in RA. Monotherapy with etanercept promotes benefit at the ACR 20 level in around 60–70% of recipients within 8–12 weeks. Etanercept reduces clinical inflammation, improves physical function and quality-of-life indices and reduces radiographic progression. In general, studies show that withdrawal rates with etanercept are lower than with placebo. The pivotal phase III study for early RA compared MTX with etanercept monotherapy in patients with RA of <3 years’ duration (Bathon et al, 2000). Both therapeutic arms improved significantly as measured by clinical response criteria and by reduced radiographic progression. Etanercept recipients exhibited marginal, but nevertheless significantly greater, improvement after 1 year than MTX recipients judged by ACR and Sharp erosion scores. Symptomatic control was evident at an earlier stage.

In a further study, clinical benefit was also shown in partial or non-responders to MTX when etanercept was used in combination with MTX (Weinblatt et al, 1999). However, the critical trial demonstrating the superior benefits of etanercept with MTX is the TEMPO study (Klareskog et al, 2004). In this large study etanercept alone, MTX alone or the two in combination were compared. Etanercept + MTX was superior in improving clinical signs and symptoms and also in suppressing radiographic progression; indeed, some patients even appeared to have an improved Sharp score. However, in this TEMPO study, most of the patients were MTX naïve, which might explain the superiority of the combination. In a recent study (ADORE) of patients with true MTX resistance, a combination of MTX with etanercept was not better than etanercept alone, which suggests that monotherapy with etanercept is possible in true MTX-resistant patients (van Riel et al, 2008). The COMET study has recently added information, determining high levels of efficacy in patients with early RA and high

disease activity (DAS28>5.1) in whom etanercept was added as initial treatment. Fifty per cent of patients receiving combination therapy and 28% of those receiving MTX monotherapy achieved clinical remission. Outcomes were particularly improved as measured by prevention of radiographic progression over 1 year, with a percentage of non-progressors of 80% in the combination arm and 59% in the MTX monotherapy group. This was translated into additional benefits in productivity gains, with less work absenteeism. Clinical and radiographic benefits were maintained at 2 years of follow-up (Emery et al, 2008a; Emery, 2009c).

Etanercept is given as an SC injection in a dose of 25 mg twice a week or 50 mg once a week.

1.3.2.3 TNF inhibitors and cardiovascular risk

There is increasing interest in the ability of TNF blocking agents to modify cardiovascular risk, which is increased in RA. Data suggest that patients with RA have a higher incidence of atherogenesis, coronary artery calcification, increased rates of myocardial infarction, cardiac-related death and reduced survival after a vascular event in comparison with the general population. This increased risk may be related to cytokine activity and it has been predicted that TNF blocking agents may reverse or retard the vascular morbidity noted above (Sattar and McInnes, 2005). TNF blocking agents reduced the risk of myocardial infarction in patients who respond to this treatment compared with those treated with a synthetic DMARD. This study had, however, a limited follow-up (maximum 1.66 years) and long-term follow-up will be necessary to confirm these results (Dixon et al, 2007).

However, TNFi can induce cardiac decompensation, and are therefore contraindicated in severe cardiac failure (please see below in the safety section).

1.3.2.4 Safety of TNF inhibitors

The safety of TNFi has now been analysed for over 10 years, and solid data from various metaanalyses and registries exist. It will be further treated in a specific section about the safety of all bDMARDs, including TNFi and non-TNFi.

1.3.3 Other biologic DMARDs (non-TNFi)

Four non-TNFi bDMARDs exist (Table 8 A. & B.) in the therapeutic arsenal, although anakinra is not commonly used for the treatment of RA.

Table 8.A: Main non-TNF inhibitors biological DMARDS used in RA

	Rituximab	Abatacept	Tocilizumab	Anakinra
Mode of action	Chimeric monoclonal Ab, anti-CD20 (B lymphocytes)	Recombinant fully human protein CTLA4-Ig Inhibits lymphocyte co-stimulation	Humanised monoclonal Ab that inhibits IL-6 receptor (membrane bound and soluble form)	Recombinant IL-1 antagonist (binds to type I IL-1 receptor)
Mode of administration	IV	IV	IV	SC
Dose	1g, repeated 14 days later Or for some centres: 500mg, repeated 14 days later With premedication: Paracetamol 1g Methylprednisolone 100 mg Dexchlorpheniramine 1 phial If relapse, to be repeated after at least 6 months Associated to MTX or other DMARD	10 mg/kg D0, D15, D30, then every 30 days SC 125 mg/week Associated to MTX or other DMARD	8mg/kg/4 weeks (min 480 mg and max 1.2g) (Dose adaptation if receiving other treatments metabolized through CYP 450 enzymes §) SC 162 mg, once/week Associated to MTX (or other DMARD), or monotherapy if MTX not tolerated	100mg/day Associated to MTX
Mean half life	20-22 days (depends on the dose and regimen)	15 days (IV)	12-15 days (8 mg/kg IV)	4-6 hours
Contraindications	- Hypersensitivity to rituximab or excipient - Severe and uncontrolled infection - Congestive heart failure (NYHA class III/IV and ejection fraction ≤ 50 %) or uncontrolled CV disease - Pregnancy (relative) and breast feeding	- Hypersensitivity to abatacept or excipient - Severe and uncontrolled infection - Pregnancy (relative) and breast feeding	- Hypersensitivity to TCZ or excipient - Severe and uncontrolled infection - Pregnancy (relative) and breast feeding	- Hypersensitivity to anakinra or excipient - Severe kidney failure (CrCl<30 mL/min) - Pregnancy and breast feeding
Precaution of use	- IgG below laboratory levels - Lymphopenia T and/or B - Hepatitis - HIV	- Past history of recurrent or chronic infection or risk factors for infection	- Diverticulitis - Active liver disease and liver failure - Neutropenia , thrombocytopenia - Dyslipidaemia	- Past history of recurrent or chronic infection or risk factors for infection - Neutropenia <1500/mm ³ - Dyslipidaemia - Cardiovascular disease

- neutropenia < 1500/mm ³	- Recent or scheduled vaccination - Diabetes mellitus (abatacept therapy can interfere with blood glucose measurements) - MGUS - Malignancy within the last 5 years*	- Cardiovascular disease - Demyelinating disease - Malignancy within the 5 last years*	- Active liver disease and liver failure

¶ Detailed information and vaccination guidelines are given in Appendix 3. †Perioperative management of bDMARDs is detailed in In-Depth Discussion 3.

1.3.3.1 Cell targeting agents in RA (anti-CD20)

The concept that directly targeting and depleting or functionally modulating circulating leucocyte subsets and/or within the target tissues, was one of the first strategies to be tested. Initial efforts focused on T cells, so agents such as anti-CD4 antibody and Campath-1H were administered, but had limited benefits in RA. The success of this approach was first achieved through the use of rituximab, an anti-CD20 chimeric monoclonal antibody that induces B cell and plasmablast depletion.

➡ Rituximab

Rituximab is a chimeric monoclonal antibody containing humanised and murine sequences in its protein structure. It is a potent cell lytic antibody developed initially for the treatment of B cell lymphoma. On binding to cells expressing CD20, rituximab induces cell death through a variety of mechanisms that include complement-mediated lysis, antibody-dependent cellular killing and apoptosis induction. The rationale for the use of rituximab in the treatment of RA is based in its potential to reduce synthesis of autoreactive antibodies, such as RF and ACPA, and impair antigen presentation to T cells as well as cytokine production. Rituximab has been shown to be efficacious in comparison with placebo in a variety of clinical studies. This has been translated into reproducible results in daily practice with a reasonable safety profile.

An initial study compared rituximab in combination with MTX or cyclophosphamide and comprised intravenous preinfusions of methylprednisolone and concomitant oral glucocorticoids (Edwards et al, 2004; Cohen et al, 2006; Emery et al, 2006). The DANCER study (Dose-Ranging Assessment International Clinical Evaluation of Rituximab in RA) established that rituximab was superior to placebo when administered to MTX refractory patients for whom other DMARDs, including biological agents, might have failed, again together with different glucocorticoid regimens (Emery et al, 2006). In the REFLEX study (Randomized Evaluation of Long-term Efficacy of rituximab in RA) inadequate responders or patients intolerant to at least one TNF blocking agent were enrolled to receive rituximab or placebo on a background of MTX (Cohen et al, 2006). In these studies the rate of ACR 20 responders at week 24 for those receiving 1000 mg of rituximab, given as two infusions 2 weeks apart on a MTX background, was variable: 73% (Edwards et al, 2004), 54% (DANCER) and 51% (REFLEX) in comparison with placebo (38%, 28% and 18%, respectively), probably owing to different inclusion criteria and allowance of various glucocorticoids regimens.

Clinical responses to rituximab may be delayed by up to 3 months and the duration of efficacy varies, with most patients experiencing a relapse after 6 and 8 months, but some remain well up to more than 15 months (Popa et al, 2007; Roll et al, 2008). Rituximab administration is followed by peripheral B cell depletion, usually assessed by the number of circulating CD19+ cells, on average 2 weeks after administration, and its serum levels fall below the limit of detection at week 16–20. This is generally associated with a gradual recovery of B cell counts and with clinical relapse in some, but not all, patients. Although there is no direct correlation between the degree and duration of B cell depletion and clinical response, repopulation generally occurs before the development of flares (Breedveld et al, 2007; Popa et al, 2007). Patients who are seropositive for RF and/or IgG ACPA have a higher probability of responding to rituximab, with better control of disease manifestations and radiographic progression (Dorner et al, 2009).

The decision as to which patient should be re-treated and when this should occur is of utmost importance. Both the SERENE (Study Evaluating Rituximab's Efficacy in methotrexate iNadequate rEsponders) and MIRROR

studies, despite different study designs, confirmed that re-treatment with a second course of rituximab (either 2×500 mg, 2×1000 mg or dose escalation) was associated with maintenance or improvement of ACR responses at week 48, as compared with week 24, and a further increase in the number of MTX inadequate responders achieving low disease activity ($\text{DAS28-ESR} \leq 3.2$) (Emery et al, 2010a; Rubbert-Roth et al, 2010). No significant differences were found between the different treatment arms, although a higher percentage of patients receiving 2×1000 mg, achieved a good or moderate EULAR response and ACR 50 and ACR 70 responses. Examining radiographic progression in MTX naïve patients with RA, the IMAGE study suggests that the 2×1000 mg regimen is better than 2×500 mg for the inhibition of joint damage during the first 24 months but after this time and up to 2 years the radiographic damage was minimal and similar between groups (Tak et al, 2011). These studies also support the efficacy of rituximab in MTX naïve (IMAGE) and MTX inadequate responders (SERENE and MIRROR).

The need for re-treatment in responders (partial or complete) should be assessed at least by 24 weeks but should not be performed before 16 weeks since there are no data informing shorter interval spacing of therapeutics. A fixed schedule regimen still lacks formal evaluation and might be associated with overtreatment of some patients (Emery et al, 2009a).

Global assessment of rituximab safety in patients treated in clinical trials, with a total of 5013 patient-years, indicated that rituximab was generally well tolerated and that the rate of serious adverse events did not increase with re-treatment or with the duration of exposure. The most common adverse events were infusion-related reactions, which decreased with successive re-treatments. The overall rate of serious infections (4.3 per patient-year, 7% of patients) was similar to that reported with other biological agents; pneumonia, cellulitis and urinary tract infection were the most common. Two cases of tuberculosis were registered in clinical trials safety databases and also six cases of progressive multifocal leukoencephalopathy. Hepatitis B reactivation has been reported in one patient, highlighting the importance of screening for HBV, including antibodies against core antigen (anti-HBc), vaccination and HBV prophylactic treatment when indicated. Immunoglobulin levels should be quantified before and during treatment as hypo-IgG (present in 5% of patients) is a predictor of severe infections (Gottenberg et al, 2010). In contrast, although IgM is the most common subtype of immunoglobulin to decrease with treatment, this effect has not been related to a higher risk of infections (van Vollenhoven et al, 2010a). Immunological response to vaccination might be less effective in patients receiving rituximab, therefore required vaccinations (HBV, tetanus and pneumococcus) are recommended at least 4 weeks before starting treatment. Human antichimeric antibodies (HACAs) were detected in 11% of patients but this does not seem to increase the risk of infusion-related reactions or loss of efficacy and indeed secondary failure to rituximab in patients who respond is uncommon. Preliminary reports also indicate that in patients who have discontinued rituximab and started other biological DMARDs the rate of serious adverse events is not increased even when the majority of patients (83%) had B cell counts below

the lower limit of normal (Genovese et al, 2010). The first reports of combination of rituximab with other biological agents have been published. Safety was the major concern. Rates of serious adverse events were similar or lower than in the non-combined trials but as yet no clear advantage in efficacy was seen (Greenwald et al, 2011; Rigby et al, 2013).

Rituximab, licensed for patients who have intolerance or inadequate response to TNFi, has therefore become an important therapeutic option for patients with RA and an update consensus has been published (Buch et al, 2011). In spite of this, better predictors of treatment outcome and a clearer insight into the mechanism of action of rituximab in patients with RA are still required, in order to provide a rational treatment schedule. Moreover, registry data will be helpful in determining the overall safety of repeated dosing in clinical practice.

➡ Other B cell targeting therapies

Other anti-CD20 antibodies that are humanised such as ocrelizumab and veltuzumab and the fully human ofatumumab, are in phase II/III trials. Neutralisation of the B cell survival and activation cytokines BLyS (or B cell activating factor (BAFF)) and APRIL is an approach that is in development. Atacicept (which blocks both the B lymphocyte stimulator (BLyS) and a proliferation-inducing ligand (APRIL) and might therefore reversibly suppress B cell function across maturation stages) has completed phase I studies and appeared to be well tolerated. However, phase II trials do not seem to support a future role for atacicept in the treatment of RA (van Vollenhoven et al, 2010b).

1.3.3.2 Costimulation blockade in RA: abatacept

Optimal activation of T lymphocytes requires signalling via the T cell receptor (signal 1) and by costimulatory molecules—the so-called ‘second signal’. The dominant pathway to provide signal 2 involves CD28 on T cells and CD80 and CD86 on antigen-presenting cells (e.g., macrophages, dendritic cells). CTLA4, which is structurally similar to CD28, can bind to CD80/CD86 with higher affinity, and can prevent the CD28-mediated delivery of signal 2 to T cells. Abatacept is a soluble recombinant fully human protein that comprises the extracellular domain of CTLA4 and the Fc portion of an IgG1 molecule that has been modified to prevent complement activation. The T cell therefore receives one single signal which tends to switch off the cell—the so-called ‘anergy’ response. The principle of costimulatory blockade is therefore to effectively switch off the T cell compartment, including naïve T cells both systemically and locally in the joint, inducing immunomodulation and downstream events, such as blocking cytokine production (TNF, IL-1 and IL-6) and B cell activation (Platt et al, 2010).

Several randomised placebo controlled clinical trials have been conducted that demonstrated significantly higher clinical responses rates after abatacept administration than with placebo in patients with active RA despite previous treatment with DMARDs (Kremer et al, 2006; Schiff et al, 2008), anti-TNF therapies (Genovese

et al, 2005; Weinblatt et al, 2007; Genovese et al, 2008a) and DMARDs or biological agents (Weinblatt et al, 2006). The most commonly used dose was approximately 10 mg/kg given at days 0, 15, 29 and every 28 days thereafter, in association with DMARDs. *The AIM study, focusing on patients with active RA despite MTX treatment, yielded 68% ACR 20 responders in abatacept recipients compared with 40% in placebo-treated patients after 6 months, rising to 73% and 40% ACR 20 responders, respectively, after 1 year; the ACR response was maintained up to 5 years. The rate of radiographic progression was reduced with a sustained pattern over the years and nearly half of the patients had no additional damage at 5 years (Kremer et al, 2006; Genant et al, 2008; Westhovens et al, 2009b). The ATTAIn study similarly demonstrated significantly higher response rates in patients treated with abatacept compared with placebo recipients, this time in an RA population for whom at least one TNF blocking agent had failed, confirming that abatacept can be used successfully in non-responders to TNFi (Genovese et al, 2005). In the ATTEST study, the first head-to-head trial between biological agents, patients were treated with abatacept + MTX, or infliximab 3 mg/kg + MTX or placebo + MTX, and although abatacept had a similar efficacy at short term (6 months), it showed better efficacy in the long term (1 year), and had an overall better safety profile. It is important to highlight that infliximab was given at a fixed dose of 3 mg/kg every 8 weeks, as the design of the trial did not allow an increase in the frequency and/or dose (Schiff et al, 2008).*

There is particular interest in the effects of abatacept in early disease. Abatacept in combination with MTX showed higher efficacy than MTX alone (ACR 70 43% vs 27%) and superior inhibition of radiographic damage in patients with early RA and poor prognostic factors who were MTX naive at 2 years (Westhovens et al, 2009a). More recently, abatacept also proved to be able to delay the progression to RA, at 1 year, in a subgroup of patients with undifferentiated/early RA. This exploratory study (ADJUST) showed that besides delaying radiographic progression, ACPA levels were reduced, supporting the concept that abatacept can modulate T cell function in early phases of the disease (Emery et al, 2010b). Furthermore, data from the French Registry ORA (Orencia and Rheumatoid Arthritis) highlighted that positivity for ACPA is associated with a better response to abatacept and a higher retention rate at 6 months (Gottenberg et al, 2012).

Approval of the abatacept subcutaneous formulation was based on a trial programme that included three randomised controlled trials and two open-label studies: ACQUIRE (MTX inadequate responders (MTX-IRs), with an MTX background); ACCOMPANY (patients who were MTX naive or MTX intolerant/failures, with or without a MTX background); ATTUNE (switching from long-term IV to SC abatacept, in patients receiving MTX or anti-TNF-IRs); ALLOW (effects on immunogenicity and safety of withdrawing and reintroducing abatacept) and AMPLE (head-to-head trial comparing SC abatacept with adalimumab, with an MTX background). The conclusion from these studies was that SC abatacept is not inferior to the IV formulation and that similar efficacy is observed with or without an IV loading dose, both at 6 months and follow-up. Furthermore,

preliminary data from AMPLE suggest that abatacept in combination with MTX has comparable efficacy to adalimumab plus MTX at 12 months (Solomon, 2012; Schiff, 2013).

Abatacept is approved by the FDA and EMA for patients with moderate to severe RA who are non-responders to DMARDs or anti-TNF therapies, both in combination with non-biological DMARDs or in monotherapy.

Abatacept is available for administration as an infusion (loading dose at 0, 2 and 4 weeks followed by monthly administration), according to a weight-tiered dosing regimen (<60 kg = 500 mg; 60–100 kg = 750 mg; >100 kg = 1000 mg); and as an SC formulation with one induction dose weight-base as above, followed by a fixed weekly 125 mg dose. Although the approved SC regimen includes a single IV loading dose, this has not been commonly used in clinical practice.

The safety profile of this agent is satisfactory. From a pooled analysis, excluding the abatacept plus etanercept trial, the number of serious infections was slightly increased compared with placebo but the overall total number of serious adverse events was similar. Higher rates of headaches and infusion reactions were also reported (Maxwell and Singh, 2010). Recently, a Cochrane review based on a meta-analysis of adverse events registered in clinical trials suggested that abatacept has a better safety profile than other biological DMARDs (Singh et al, 2011a). Concerns about a possibly increased risk of cancer, taking into account the mechanism of action of the drug, have not been confirmed in the safety data base from phase 3 trials or in registries. An additional study compared the combination of abatacept plus etanercept with etanercept plus placebo showing no benefit of this association and an increased risk of serious adverse events (Weinblatt et al, 2007). Safety data from SC abatacept trials have highlighted lower serious infectious rates than with the IV formulation, without significant differences in other adverse events with the exception of injection site reactions (3.5%). Cases of tuberculosis and psoriasis have been described. The risk of immunogenicity might be slightly lower with SC abatacept, and switching from IV to SC administration does not seem to be associated with a significant increase in immunogenicity (Schiff, 2013).

1.3.3.3 IL-6 blockade: Tocilizumab

Several lines of evidence support the role of IL-6 in RA pathogenesis. This encouraged the development of tocilizumab, the first humanised monoclonal antibody that inhibits IL-6 receptor signalling through both its membrane bound (mIL-6R) and soluble (sIL-6R) forms. IL-6 expression is greatly increased in the synovial tissue of patients with RA and a correlation between serum and synovial fluid IL-6 levels and disease parameters has been identified (Madhok et al, 1993; Sack et al, 1993). Studies in mice give further support to the role of IL-6 in RA pathogenesis, suggesting that IL-6 is necessary for the induction of arthritis in the collagen-induced arthritis model and that IL-6 signalling inhibition with an antibody against IL-6R abrogates the inflammatory process. The blockade of IL-6 effects results in marked reduction acute phase reactants

produced by the liver and improvement of chronic inflammation anaemia due to hepcidin. It is not yet clear what happens to cell survival after binding of antibodies against IL-6R and further research is required.

The safety and efficacy of tocilizumab have been assessed in five phase III double-blind randomised controlled clinical trials that included more than 4000 patients with RA with moderate to high disease activity. In most of these studies the primary end point was the ACR 20 response at week 24 and it was found that intravenous administration every 4 weeks of 8 mg/kg tocilizumab was better than 4 mg/kg. *The AMBITION study demonstrated superiority of tocilizumab 8 mg/kg monotherapy versus MTX, in patients for whom MTX or biological agents had not failed previously (70% vs 53%) (Jones et al, 2010). Tocilizumab (8 mg/kg) in combination with MTX was also effective in MTX inadequate responders compared with placebo in the OPTION study (59% vs 26%) (Smolen et al, 2008). Similarly, when tocilizumab was added to DMARDs in monotherapy or in combination (76% receiving MTX), ACR 20 responses improved as compared with DMARDs alone (61% vs 25%), showing benefits in a more clinical representative population (TOWARD study) (Genovese et al, 2008b). The RADIATE trial demonstrated that 50% of the patients refractory to anti-TNF therapy achieved an ACR 20 response when treated with tocilizumab, as compared with 10% in the placebo arm (Emery et al, 2008b). Finally, protection from structural damage was evaluated in the LITHE trial at 52 weeks, which showed inhibition of radiographic progression as assessed by the modified Sharp score in the actively treated patients compared with placebo. Furthermore, this study highlighted an increase in the number of patients achieving DAS28 remission up to 2 years (Fleischmann et al, 2010). The results from the AMBITION study clearly showed that tocilizumab monotherapy is better than MTX at 24 weeks (Jones et al, 2010). Moreover, tocilizumab monotherapy also demonstrated non-inferiority to the tocilizumab combination with MTX in patients refractory to DMARDs (ACT-RAY) (Dougados et al, 2011) or in association with other DMARDs in DMARD or TNFi inadequate responders (ACT-SURE) (Bykerk et al, 2011). The absolute number for several end points in ACT-RAY—namely, rates of remission and radiographic progression, showed, however, slightly better results in favour of combination therapy. In the recent trial (ADACTA) comparing tocilizumab and adalimumab, both in monotherapy, tocilizumab demonstrated clinical superiority (Gabay et al, 2013). Despite the cautious interpretation of these data, as tocilizumab was not compared with an adequate comparator, i.e., ADA + MTX, it further supports the efficacy of tocilizumab as monotherapy. Together these data potentially position tocilizumab as a candidate for biological monotherapy when for whatever reason (e.g., other adverse effects and contraindications to other agents) this option is considered. From the analysis of data of patients receiving tocilizumab 4 mg/kg/month and 8 mg/kg/month there seems to be a clinical (even if non-significant) superiority of the higher doses. Use of the higher dose is further supported by an increased risk of anaphylactic reactions when lower doses are given.*

These data from clinical trials led to the approval of tocilizumab for the treatment of moderate to severe RA, in combination with MTX, in patients who have inadequate response to one or more anti-TNF agents (USA and

Europe) or DMARDs (Europe). Tocilizumab, 8 mg/kg (or 4 mg/kg in some areas at the start), is given intravenously every month in combination with MTX or other DMARDs. The maximum recommended dose is 800 mg for people weighing ≥ 100 kg. EMA has further considered the use of tocilizumab in monotherapy when MTX treatment is not tolerated or contra indicated. A recent consensus statement has been published (Smolen et al, 2013). Owing to the impressive reduction in CRP, it is important, while monitoring, to consider the different components of DAS28 and other scores besides CRP or to use the Clinical Disease Activity Index preferentially.

Safety concerns are in some respects similar to those of other biological DMARDs. So far, a slightly increased risk of infections and rare infusion-related reactions have been reported, which seem to be higher when low doses are used. Glucocorticoids should be tapered as soon as possible as they increase the risk of infection. Other reported adverse events might be more specific to the tocilizumab mechanism of action, including a decrease in neutrophils and platelet counts and an increase of liver enzymes (especially when combined with MTX) (**Table 10**). Recommendations are available on how to monitor the process according to laboratory levels and when treatment should not be started or should be interrupted. An increase in low-density lipoproteins (LDL) and high-density lipoproteins (HDL) has been seen but the risk of cardiovascular events in patients with RA treated with tocilizumab has not been quantified. The MEASURE study suggested that the changes in lipid particles mainly comprise creation of fewer atherogenic species—the clinical consequences of these observations, however, will probably require formal clinical endpoint follow-up. The rate of lower intestinal perforations (LIP) at 8 mg/kg was greater than in placebo recipients in randomised control studies, and a recent work on data from registries established that the incidence rates of LIP under TCZ found in the “real world” study are in line with those seen in randomised controlled trials of TCZ and higher than in all other DMARD treatments (Strangfeld, 2016). To ensure safe use of TCZ in daily practice, physicians and patients should be aware that, under TCZ, LIP may occur with mild symptoms only and without CRP elevation (because it is impeded by IL-6 blockade). Hence, caution must be used in patients with previous diverticulitis (Singh, 2011b; Strangfeld, 2016) (**Table 10**).

Recommendations concerning hepatitis B virus (HBV) or hepatitis C virus (HCV) infections and tuberculosis are similar to those for other biological agents. Finally, co-prescription of drugs metabolized by the CYP450 enzymes requires adjusting their dosage upon tocilizumab initiation or discontinuation. The most widely used medications metabolised by CYP450 are listed in **Table 9**. The full list is available online at <http://medicine.iupui.edu/clinpharm/ddis>

Table 9: Example of medications metabolised through CYP450 isoenzymes.

Principal interactions	Medications
CYP 1A2	Theophylline
CYP 2C9	Phenytoin
	Warfarin
CYP2C19	Benzodiazepines (alprazolam, diazepam, midazolam, prazépam, clorazepate...)
CYP 3A4	Cyclosporine
	Atorvastatin, simvastatin
	Calcium channel blockers (amlodipine, diltiazem, nifedipine, felodipine, isradipine, nifedipine, nitrendipine, bepridil, verapamil...)

Table 10: Precautions of use, prevention and management of neutropenia, thrombocytopenia, elevated liver enzymes and lower intestinal perforations in patients with rheumatoid arthritis treated by tocilizumab

Haematological abnormalities	
<ul style="list-style-type: none"> Neutrophils: 500-2,000/mm³ Platelets: 50-100,000/mm³ 	<ul style="list-style-type: none"> No contraindication; use TCZ with caution
<ul style="list-style-type: none"> Neutrophils: < 500/mm³ Or platelets: <50,000/mm³ 	<ul style="list-style-type: none"> The use of TCZ is not recommended

<ul style="list-style-type: none"> In case of abdominal symptoms 	<ul style="list-style-type: none"> Discontinue TCZ therapy and refer the patient to a gastroenterologist for diagnosis and treatment The evaluation by a gastroenterologist should be obtained very promptly in patients with a fever, bleeding, or abnormal abdominal physical findings
<ul style="list-style-type: none"> In patients who experience diverticulitis while on TCZ therapy 	<ul style="list-style-type: none"> The available data are inadequate to recommend re-starting the drug Prophylactic surgical resection should be considered.

TCZ, tocilizumab; ALAT, alanine aminotransferase; ASAT, aspartate aminotransferase; ULN, upper limit of normal (ULN)

An antibody targeting IL-6R (sarilumab, Bridgewater, Nj, USA), and other agents targeting directly IL-6, are in development.

1.3.3.4 Anakinra (IL-1Ra)

Anakinra is a recombinant IL-1 antagonist which does not induce signalling upon binding to type I IL-1 receptor and therefore can act as a competitive antagonist to IL-1. Two randomised controlled double-blind trials provide the core evidence of benefit in RA. *Monotherapy leads to an ACR 20 response in 40% of patients at 8–12 weeks, with significantly fewer achieving significant improvement at ACR 50 and ACR 70 levels, and delays radiographic progression. In the pivotal phase III study, combination of anakinra (1 mg/kg/day) and MTX produced a higher ACR 20 response rate (42%) as compared with 23% in MTX only recipients (Bresnihan, 2001). From these studies a fixed dose of 100 mg/day in combination with MTX was selected and a post-approval third trial confirmed similar efficacy to that seen in previous trials. Adverse events were similar in nature and frequency to those with placebo. In the phase III study 13.6% discontinued because of an adverse event. Injection site reactions were common (>60% in trials) and, although mostly of mild to moderate severity, caused withdrawal in 7% of recipients. The severity of injection site reactions reduced with treatment cycles. Allergic reactions to anakinra were rare (<0.5%). Minor (about 30%, especially upper respiratory) and major infections (about 2%) were slightly more common than in placebo recipients in controlled trials. Neutropenia has occasionally been seen.*

These data supported the licensing of anakinra but in clinical practice it is not widely used, as it appears to be less effective than TNF blockers in RA (Thaler et al, 2009). Furthermore, the combination of anakinra and etanercept provided no additional benefit to etanercept alone and was associated with increased safety concerns (Genovese et al, 2004).

Other reagents targeting IL-1—including anti-IL-1 antibodies, anti-IL-1R and IL-1 ‘TRAP’ (consisting of IL-1 receptors and an Fc subunit)—have similarly failed to show clear-cut efficacy in RA.

1.3.4 Safety of biological agents (TNF blockers and non-TNF blockers)

The safety of TNFi has now been analysed for over 10 years, a little less for the non-TNF blockers. First, randomised controlled trials and their extension phases are now available (Ramiro et al. 2013, Singh et al. 2016 [Cochrane Network metaanalysis]). Then, important data from daily clinical practice has been established from the various national or international registries, such as the British BSR registry, the Swedish ARTIS or SSATG registry, the German RABBIT registries, the Spanish BIOBADASER registry, or the North-American RADIUS or CORRONA registries.

Although each molecule might have specificities (which are detailed above in each drug section), the majority of adverse events are similar for all bDMARDs (TNFi and non-TNFi), and so is their management (**Table 11**). Thus the pre-screening and monitoring is globally the same (**Table 7 and 8**). However, safety of TNFi was the better studied, and therefore stands as a reference for the description of global safety in this section.

➞ Localised skin reactions

They concern all the TNFi and non-TNFi administrated sub-cutaneously. They are frequent (10 to 50 %), and polymorphous: pain, pruritus, red patch or haematoma at the injection points. They are usually easily managed topically and don't require to stop the drug. Certolizumab pegol seems to be less prone to these localised skin reactions, probably because pegylation doesn't induce activation and degranulation of mast cells.

➞ General reactions

These general effects have mainly been described with infliximab, at the moment or during the two hours following the infusion. Several symptoms have been reported: headaches, fever, shiver, nausea, vagal reactions, pruritus, urticaria, pleuro-cardiac reactions. These manifestations usually occur during one of the 3 first infusions, and rarely require stopping the treatment. However, rare severe infusion reactions to infliximab have been reported, and appropriate resuscitation facilities should be available if needed.

➞ Infections

TNF α , and thus IL-1 and IL-6, play an important role in the human defence against infectious agents. So do T- and B-lymphocytes. The initial expectation that blocking a cytokine of such fundamental importance in the immune function would lead to profoundly immunosuppressed patients has not proved to be true. Infectious adverse events in randomised controlled trials are, in general, of a similar nature and frequency in patients treated with TNF blockers as in placebo-treated patients. However, registry datasets, post-marketing reports

and meta-analyses have highlighted a small, but real, increased risk of serious infections with the use of TNFs inhibitors in comparison with synthetic DMARDs (Ramiro et al. 2014; Yun et al. 2014; Zink et al. 2013). Furthermore, when an infection occurs, it can be particularly severe and life-threatening. The estimated risk of severe infection under TNFi is 3 to 5 for 100 patient-years. This risk is similar among infliximab, adalimumab and etanercept, and higher in the first 6 months of treatment, particularly in older people, glucocorticoid users and those who have other comorbidities and previous infections.

Table 11.A: potential adverse events of biological Disease-Modifying Antirheumatic Drugs (bDMARDs) and their management

Medical problem	Clinical expression	Medical response
Localised skin reactions	Pain, pruritus, red patch or haematoma at the injection points	<ul style="list-style-type: none"> Antihistamine treatment, local steroid therapy Get the biological treatment out of the fridge one hour before injection, and inject slowly (1 min) No need to stop the biologic in the vast majority of cases
General reactions	<ul style="list-style-type: none"> Headaches, fever, shiver Nausea, vagal reactions Pruritus, urticaria, Hypotension, pleuro-cardiac reactions Bronchospasm, anaphylactic shock (rare) 	<ul style="list-style-type: none"> Prevention: monitoring of the infusions (heart rate, blood pressure) Mild-to-moderate reactions: 50% decrease of the infusion rate; if needed, IV administration of an antipyretic agent (acetaminophen) or antihistamine; discontinuation if the symptoms persist despite the slower infusion rate Severe reactions: immediate permanent discontinuation of the infusion; appropriate resuscitation measures; adrenalin, antihistamines and glucocorticoids in patients with anaphylaxis; transfer to ICU if needed; definitive contraindication of the molecule
Bacterial or opportunistic infection	Not exhaustive: <ul style="list-style-type: none"> Fever, shiver, asthenia Cough, dyspnoea Skin rash Urinary burning or urgency Back pain (pyelonephritis, spondylodiscitis) Abdominal pain (diverticulitis) Hyperleucocytosis, acute phase response Fever absence is possible and must not reject the hypothesis of an infection 	<ul style="list-style-type: none"> Stop the treatment Look for severe clinical signs (high fever, hypotension, septic shock) that would impose a transfer to ICU Take samples for bacterial examination, according to the localisation of the infection (e.g. urinary). If respiratory signs, do an X-ray of the chest Antibiotics adapted to the infection type, and if possible to the antibiogram Once the infection treated, wait at least 1 week for mild infections (up to one month in case of severe infection) before reintroducing the drug under close monitoring; in case of infection reoccurrence, consider permanent interruption In case of severe infection, report to pharmacovigilance <ul style="list-style-type: none"> Prevention: Vaccination according to recommendations¶. Paradoxal drug-induced psoriasis	<ul style="list-style-type: none"> Psoriatic skin eruption (polymorphic) 	<ul style="list-style-type: none"> Reconsider the diagnosis: real RA? Psoriatic arthritis? Look for personal and familial past history Confirmation of the diagnostic of paradoxal drug-induced psoriasis

		<ul style="list-style-type: none"> ▪ <u>In case of mild manifestations:</u> most of the cases can be managed locally without TNFi discontinuation ▪ <u>In case of more severe manifestations not controlled locally:</u> consider switching for another TNFi or bDMARD*
Dental care	▪ Variable	<ul style="list-style-type: none"> ▪ Regular oral hygiene and visits to the dentist are recommended. Patients with oral or dental health problems should receive appropriate treatment before starting therapy. ▪ <u>Routine dental care (cavities, scaling):</u> Prophylactic antibiotic therapy can be suggested. ▪ <u>Dental procedures associated with a risk of infection (extraction, apical granuloma, abscess...):</u> the infusion should be postponed and prophylactic antibiotic therapy given ▪ <u>Implants:</u> no contraindication to dental implants provided the alveolar ridge is adequate and the risk of infection is not unreasonably high

*RA, rheumatoid arthritis; ADA, anti-drug antibodies; MTX, methotrexate; csDMARD, conventional synthetic Disease-Modifying Antirheumatic Drug; bDMARD, biological Disease-Modifying Antirheumatic Drug; TNFi, Tumour Necrosis Factor inhibitors; ANA, antinuclear antibody; anti-DNA Ab, anti-deoxyribonucleic acid antibodies; MRI, Magnetic Resonance Imaging; NYHA, New York Heart Association. *In a patient, paradoxal drug-induced psoriasis can occur with only one TNFi molecule or there might be a “class effect”. The risk could be lower with soluble receptors when compared to monoclonal antibodies.*

The attitude to adopt in front of particular situations can vary from a country to another, and can be found in local guidelines for each country. As an example, clinical tool guides elaborated by the French “Club Rhumatismes et Inflammations” can be found in English version at <http://www.cri-net.com>

Different factors may contribute to this decrease in risk over time, including the drop out of susceptible individuals, upregulation of cytokines to compensate for the lack of TNF, reduction of glucocorticoids, etc. (Listing et al, 2005; Askling et al, 2007; Galloway et al, 2011*). The physician should particularly fear serious bacterial complications, in particular pulmonary, but also viral (especially Herpes group viruses), fungal or opportunistic (Singh et al. 2011).

Of particular importance, patients are more prone to intracellular bacterial infections (e.g., Mycobacterium tuberculosis), mainly owing to reactivation of latent infection (Nam et al, 2010). This increased risk has first been described for infliximab, but has been now reported for all the TNFi, even etanercept, although evidence suggests that this risk is higher with monoclonal antibodies. Indeed, the risk of tuberculosis reactivation is 2 to 4 times lower in patients treated with etanercept than with monoclonal antibodies (Tubach et al. 2009). One explanation could be linked to the different effects of the two drugs on the production of type 1 interferon and on the monocytes-macrophages: the monoclonal antibodies induce a lysis of these cells in a complement-dependent manner after binding the TNF, while the soluble receptor does not. The incidence of tuberculosis

may be significantly reduced (up to 80%) by screening and administration of appropriate prophylaxis (Carmona et al. 2005). Hence, a systematic search for a history or risk factors of tuberculosis, a clinical examination, a chest X-ray, and tuberculosis test (Tuberculin skin test or Interferon-Gamma Release Assays (IGRAs), according to local guidelines), should be done prior to starting a treatment with a bDMARD (**Table 7 and 8**). If necessary, an appropriate prophylaxis according to local guidelines on duration, choice of antibiotic and threshold for treatment should be carried out.

Because RA patients, especially when receiving a bDMARD, are at higher risk to develop an infection, they should be vaccinated according the guidelines that will be detailed in **Appendix 3**. Of importance, the use of live vaccines in patients receiving bDMARDs is contraindicated. Perioperative management depends on the half-life of the drug (**Table 7, 8 and In-Depth Discussion 3**).

➡ Malignancies and lymphoma

Immunosuppressive agents have been associated with an increased risk of specific types of cancers, such as lymphomas (often related to viral reactivation), skin cancer (due to sun exposure) and cervix cancer (related to HPV16). On the basis of such observations, there could be a theoretical risk of specific cancers with immunomodulating agents, such as bDMARDs (Bongartz JAMA 2006; Pham et al. 2011). Data from both British and Swedish registries suggest that the overall risk of malignancies is not increased in a short–medium follow-up period. There seem to be an exception for skin cancers (other than melanoma) for which a 2 fold increased risk has been identified (Mariette et al. 2011). Therefore, a monitoring with an annual dermatologic consultation should be proposed under these therapies.

Concerning the lymphoma, different studies have shown that the risk of lymphoma is higher in RA patients treated by TNFi than in patients who don't receive this therapy (Furst et al. 2012). However, the risk of lymphoma is increased in RA, especially when the disease is severe, and the relative risk for lymphoma does not seem to be further increased compared with the increased risk already seen in patients with RA (Askling et al, 2009a; Askling et al, 2009b; Dixon et al, 2010). Hence, the increased risk under TNFi could be due to a more severe disease (which justified the TNFi prescription) rather than to the drug itself. However, the French observatory RATIO showed an increased frequency of lymphoma in patients treated with monoclonal antibodies when compared to etanercept (Mariette et al. 2011).

Although the risk is not clearly increased, the physician should be very cautious while prescribing TNFi in patients with past history of malignancy of lymphoma. There is not clear cut-off, but the empiric period of 5 years has been proposed. However, this period might vary from to a centre to another, and should be modulated for each person medical history.

➡ Immunogenicity and autoimmunity

Antibodies directed against infliximab have been found in 24 to 37% of patients. These patients are more prone to develop general reactions during the perfusion. The systematic adjunction of methotrexate decreases the incidence of these antibodies. Other antibodies directed against adalimumab and the other monoclonal antibodies have also been reported, while the induction of antibodies directed against etanercept are still under debate. Such Anti-Drug Antibodies (ADA) can be neutralising: they can reduce the serum concentration of these drugs and hence reduce their efficacy at short and medium term. On the long term, they reduce the therapy maintenance of the TNFi (Bartelds et al. 2011). The immunogenicity of tocilizumab and abatacept has been poorly studied; the occurrence of ADAs to TCZ seems to be a rare event (Sigaux 2016).

Antinuclear and anti-DNA antibodies induced by TNFi have been reported. Most of the time, these antibodies don't have clinical repercussion, although rare drug-induced lupus is possible. However, these forms of lupus are usually mild, and often regress when the TNFi is stopped. Increased risk of demyelination conditions was also reported, and patients with a previous demyelinating disease should not usually receive TNF blocking agents. Although TNFi are effective for the treatment of psoriasis, a paradoxal drug-induced psoriasis has been observed in patients with RA treated with anti-TNF drugs, and can occur even if the patient has no personal or familiar medical history of psoriasis. When the skin eruption is reluctant to local therapy, it might sometimes require changing to another TNFi or bDMARD.

➡ Other adverse events

A study in patients with congestive cardiac failure indicated cardiac function deterioration in infliximab recipients (Daniel et al, 2002). Anti-TNF agents should not be given to patients with New York Heart Association (NYHA) class III/IV cardiac failure.

Transaminase elevation, leukopenia and thrombocytopenia have been reported. Some patients might experience a paradoxical fatigue or weight gain. Several cases of vasculitis or granulomatosis (sarcoidosis, Crohn disease...) have also been described.

1.3.5 Switching between bDMARDs

This concept will be detailed below, in the strategy section.

Summary points: bDMARDs

- ➔ When initial treatment with MTX (or with other csDMARDs if contraindication or adverse effect prevents the use of MTX) has failed, bDMARDs should be started if poor prognostic features are present (RF and/or ACPA, early erosions, high disease activity) (2016 EULAR recommendations update, please see the strategies section below).
- ➔ bDMARDs regroup molecules that inhibit either a cytokine (TNF inhibitors) or its receptor (tocilizumab, inhibiting IL-6receptor) or the T lymphocyte costimulation (abatacept). Rituximab induces B lymphocyte depletion (anti-CD20 monoclonal antibody).
- ➔ Anakinra is not commonly used in the treatment of RA, although it has proven clinical and structural efficacy.
- ➔ bDMARDs share common adverse events, mainly an increased risk of infection (Table 11). Hence, screening before treatment, vaccination according to guidelines and regular monitoring should be done (Tables 7 and 8).
- ➔ No current data enables to establish that a bDMARD is more efficacious than another and that it should be given first. However, owing to considerable experience in clinical practice, TNFi are, in many countries, often considered the first-choice biological agent.
- ➔ bDMARDs should be used in combination with a csDMARD, because this combination is more efficacious than bDMARD monotherapy. Furthermore, combination decreases the risk of immunogenicity.
- ➔ In patients who have a contraindication to csDMARDs and thus require bDMARD monotherapy with biological agents, tocilizumab may be the preferred choice (keeping in mind that tocilizumab combination with csDMARD is still more efficacious than tocilizumab monotherapy).
- ➔ Owing to their different half-lives, perioperative management is also variable for different bDMARDs (table 7, 8 and In-Depth Discussion 3).

1.4 Targeted synthetic DMARDs (tsDMARDs)

Target synthetic DMARDs are targeted molecules interfering with specific signal-transduction. The only tsDMARDs currently available in the treatment of RA are Janus-kinase (JAK) inhibitors.

1.4.1 Mechanism of action

JAKs are a family of non-receptor protein tyrosine kinase that affect intracellular signalling through their association with transcription factors known as signals transducer and activator of transcription (STATs), otherwise known as the JAK-STAT pathway. JAKs are constitutively bound to their associated receptors and are activated when the corresponding cytokine or growth factor binds to its receptor. Activated JAKs phosphorylate the tyrosine residues on the STAT proteins, allowing dimerization of the STATs, which then migrate into the cytoplasm and then translocate into the nucleus, allowing for transcription of their target genes (and mainly transcription of proinflammatory genes in RA pathophysiology) (Figure 9).

Within the family of JAKs, there are four members: JAK1, JAK2, JAK3 and tyrosine kinase 2 (Tyk2) (Kelly 2013). JAK1, JAK2 and Tyk2 are fairly ubiquitously expressed in mammalian cells, whereas JAK 3 has a more limited

repertoire, with expression primarily on haematopoietic cells (Kelly 2013). JAK pathways are normally involved in growth, survival, development and differentiation of a variety of cells, but are crucially important for immune and haematopoietic cells (Hodge 2015).

In RA, B cells, T cells, macrophages and other leukocytes infiltrate the synovium in response to pro-inflammatory cytokines and chemokines, leading to inflammation and tissue destruction. Cytokine signalling via JAK pathways leads to further induction of inflammatory gene expression, which continues the loop of inflammatory signalling. Inhibiting cytokine signalling by inhibiting the JAK pathways may, therefore, interrupt the cycle of leukocyte recruitment, activation and pro-inflammatory cytokines at site of inflammation (Hodge 2015) (Figure 9). Hence, JAK inhibitors act on innate and adaptive immunity, through interfering with signal transduction and thus cell activation elicited by interleukin (IL)-6, granulocyte-monocyte colony stimulating factor, interferons (type I and II), and common γ -chain cytokines (such as IL-2, 4, 7, 9, 15 and 21) (Schwartz et al, 2016).

1.4.2 Tofacitinib

Tofacitinib (Xeljanz®) is a pan-JAK inhibitor, which has been approved in the USA, Switzerland, Japan, Russia and many other countries for use in RA after failure of csDMARDs. It has not been yet (in 2016) been approved for use within the European Union.

➡ Efficacy in RA

Tofacitinib is efficacious clinically and structurally in RA: the efficacy of tofacitinib plus methotrexate at the approved dose of 5 mg twice a day appears to be similar to that of biologics (Fleischmann 2010; van der Heijde et al, 2013; Lee et al, 2012; Smolen et al, 2016). Intriguingly, tofacitinib monotherapy is clinically superior to MTX (Lee et al, 2014; Fleischmann et al 2016).

➡ Tofacitinib prescription in practice

Tofacitinib, combined with a csDMARD or used in monotherapy, is indicated as second-line treatment for moderate-to-severe active RA in patients with an inadequate response or intolerance to MTX. It is given orally, 5mg twice a day. In case of insufficient clinical response, the dose can be increased to 10 mg twice a day. The intakes should be regular, if possible at the same hour every day. Screening investigations and monitoring are globally the same as for bDMARDs.

Figure 9. Simplified representation of the intracellular JAK-STAT signalling pathway, and mechanism of action of JAK inhibitors in the treatment of RA. JAKs are constitutively bound to their associated receptors and are activated when the corresponding cytokine or growth factor binds to its receptor. Activated JAKs phosphorylate the tyrosine residues on the STAT proteins, allowing dimerization of the STATs, which then migrate into the cytoplasm and then translocate into the nucleus, allowing for transcription of their target genes. JAK inhibitors hence block the synthesis of pro-inflammatory cytokines by blocking the transcription of pro-inflammatory genes.

JAK, Janus kinase; STAT, signals transducer and activator of transcription; P, phosphorylated.

➡ Safety

Currently available data is based on phase II and III trials, and little is known about its long-term safety. Herpes zoster infection in particular appear to be more common than seen with TNF inhibitors (van Vollenhoven et al, 2012; Fleischmann et al, 2016); several cases of tuberculosis (TB) and non-TB opportunistic infections have been reported; lymphocytopenia and anaemia also occur, and haemoglobin levels appear to increase less upon clinical improvement than seen with csDMARDs and bDMARDs. Of note, the serum creatinine increase, the elevation of transaminases and hypercholesterolemia (LDLc increase) is higher than in placebo (Riese et al, 2010; Fleischmann et al, 2016).

1.4.3 Other JAK inhibitors

➡ Baricitinib

Baricitinib is a selective JAK1-JAK2 inhibitor, which is currently in phase 3 trials, and has not yet been approved in any jurisdiction. It appears to convey a similar range of efficacy as the biological DMARDs and tofacitinib (ref). Interestingly, however, baricitinib plus MTX elicited a superior clinical and functional (although not

structural) outcome compared with adalimumab plus MTX (Taylor et al 2015). Moreover, the roughly 15% ACR70 response rate in patients whose disease had previously not responded to or not tolerated a TNF inhibitor was similar to the response rate in patients who had not responded to multiple biologics (Genovese et al, 2016).

➡ Filgotinib

Filgotinib is a selective JAK 1 inhibitor, which is currently under phase 3 trials.

2. Therapeutic strategies

2.1 General approach to the treatment of RA

The care and treatment of RA is complex, it involves pharmacological and non-pharmacological treatment, and should be multidisciplinary. This has been comprehensively summarized in the EULAR guidelines for early or established RA management (Combe 2010; Smolen et al, 2010; Smolen et al, 2014*). New guidelines 2016 will soon be published, and are available in a PDF form on the EULAR website (<http://www.eular.org>, Smolen et al, 2016*).

The 2016 updated EULAR recommendations have established four overarching principles:

- ➡ *Treatment of RA patients should aim at the best care and must be based on a shared decision between the patient and the rheumatologist.* Shared decision-making includes the need to inform the patient of the risks of RA and the benefits of reaching the targeted disease activity states as well as the pros and cons of respective therapies (Smolen et al, 2014*; Smolen et al, 2016*). Hence, the patient should be directly involved in the treatment decisions, which implies upstream the need for a good patient education.
- ➡ *When therapy needs to be adjusted, factors apart from disease activity, such as progression of structural damage, comorbidities and safety issues should be taken into account.* This overarching principle intends to raise awareness of several points:
 - Reaching the outcome of low disease activity or remission is not an absolute prerequisite, and it is equally important to account for comorbidities and other contraindications when targeting a good outcome.
 - Conversely, high disease activity is typically associated with comorbidities. A decrease of 5–9 years in life expectancy occurs in RA, mainly owing to increased cardiovascular morbidity, infection and lymphoma (Gonzalez et al, 2008; Baecklund et al, 2006). Evidence suggests that disease activity and severity have a significant effect on these outcomes and that effective

therapeutic intervention can modulate them (Choi, 2002; Westlake, 2010; Westlake, 2011). Hence, regular assessment of cardiovascular (measurement of blood pressure, lipid profile, body mass index, plasma glucose and recording of cardiovascular family history) and of risk factors for other medical complications (serious infection, cancer, fragility fractures and gastrointestinal haemorrhage) should be systematic, as well as their care. Smoking cessation should comprise part of the overall approach to a patient with RA (Goodson et al, 2008), because it has been recognised as a critical factor for the development of RF-positive RA, for the production of ACPA and is associated with more severe disease and reduced response to treatment.

- Finally, some patients with low disease activity may still develop seriously progressive radiographic joint damage, so after potential lag periods have been accounted for to recognise progression (Aletaha D, 2009), such patients may then need intensification therapy. Hence, early evaluation of erosive changes is essential (through plain hand and feet X-ray examinations complemented if needed by high-resolution US and/or joint MRI), and structural damage progression should be reassessed periodically (especially in the beginning of the disease, as the progression rate of erosion is the highest in the two first years).
- ➡ *Rheumatologists are the specialists who should primarily care for RA patients.* There is clear evidence that continuous care under the auspices of an experienced rheumatologist improves functional outcomes (Smolen et al, 2010; Smolen et al, 2014*). However, the care and treatment of RA should be multidisciplinary, and it involves a lot of other health professionals (primary care physician, nurse, physiotherapist, podiatrist, psychologist, occupational therapist, social worker...) whose role will be developed in **In-Depth Discussion 1** (www.eular-onlinecourse.org). These health professionals are also of great help for the achievement of non-pharmacological and local therapies, which are still useful in everyday management of RA (see in **In-depth Discussion 3** www.eular-onlinecourse.org).
- ➡ *RA incurs high individual, societal and medical costs, all of which should be considered in its management by the treating rheumatologist.*

2.2 EULAR recommendations for the management of RA with cs and bDMARDs

These recommendations are summarised in the algorithm presented in **figure 10**.

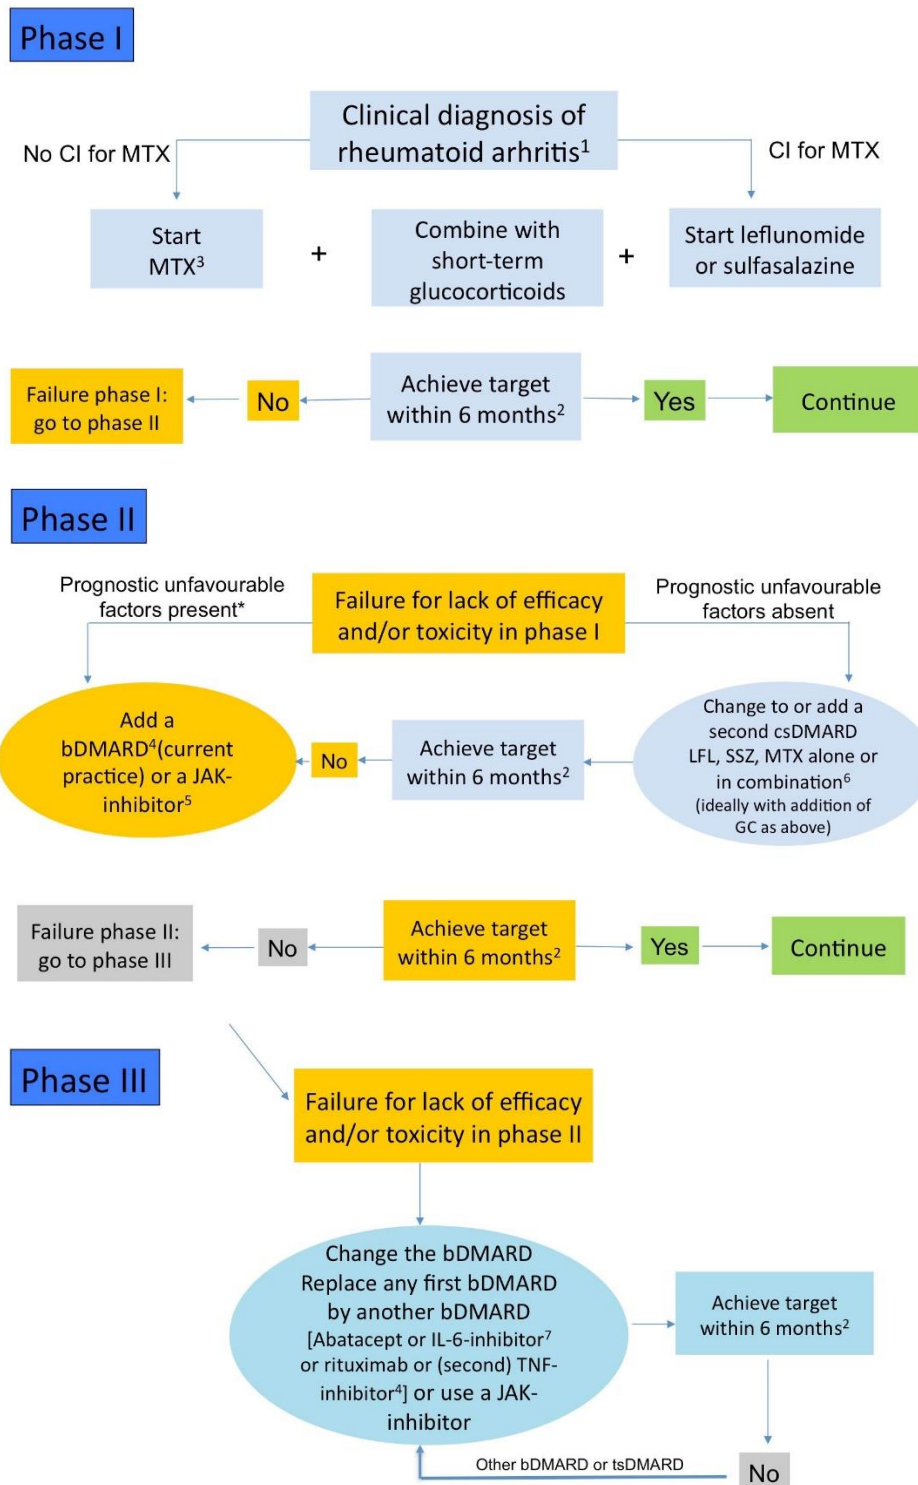

- ➡ *Therapy with DMARDs should be started as soon as the diagnosis of RA is made.* This implies the necessity to make an early diagnosis. To this end, the 2010 ACR-EULAR classification criteria should be used to support diagnosis and facilitate early introduction of effective therapy in RA (Radner et al, 2013). At time of diagnosis, the physician should be particularly cautious in identifying the patients at higher risk (Combe

et al, 2007), although there is as yet no clear paradigm to predict those patients with the poorest prognosis. Several features should, however, raise the clinical “index of suspicion”. Thus, rheumatoid factor (RF)-positive and/or anti-cyclic citrullinated peptide antibodies (ACPA)-positive patients, those possessing the shared epitope in the major histocompatibility complex class II region (not searched in regular practice) and those with high acute phase response, poor function, high swollen and tender joint counts, rheumatoid nodules, Felty syndrome, rheumatoid vasculitis, interstitial lung disease and erosion at presentation tend to do less well. Measurement of the autoantibody status (RF and ACPA) should be systematic at baseline and recheck later, if initially negative.

The era of personalised medicine is however not yet upon us, and at this stage an individual calculation of absolute risk is not possible in general practice. Matrix-based approaches have been developed and offer a rational approach to calculating the relative risk of progression based on baseline features (Figure 11a) (Vastesaeger et al. 2009). It has been hypothesized that the use of prediction matrices of risk of rapid radiographic progression (RRP) for early RA in clinical practice could help to better rationalise the first line of treatment. However a recent work on matrices to identify patients at risk of RRP tested in the ESPOIR cohort showed that these matrices seemed to perform moderately, and there was no matrix that showed clearly superior performance (Granger et al. 2016) (Figure 11b). Several research initiatives comprising transcriptomic (microarray), metabolomic and proteomic approaches are ongoing that may better help to identify those RRP patients in the future.

- *Treatment should be aimed at reaching a target of sustained remission or low disease activity in every patient.* This implies treatment to target through tight-control, and the use of composite tools to achieve remission according to the ACR-EULAR remission criteria (Felson et al, 2011) (please see **Table 1** in the introduction of this course). When achieving remission is not possible, low disease activity defined by composite measures is a good alternative goal for many patients who cannot attain remission even today, especially those with long-standing disease who actually constitute the majority of patients in clinical care. Indeed, although somewhat worse than remission, low disease activity conveys much better functional and structural outcomes than moderate or high disease activity. Furthermore, a significant proportion of patients in clinical practice still do not attain a state of remission (ref), so once any patients has reached a low disease activity that is close to remission (Mireau et al 2007; Kiely et al, 2011), the individual disease activity variables have to be considered in detail before major therapeutic changes are made (Smolen et al, 2014*).

Figure 10. Algorithm based on the 2016 EULAR recommendations on RA management.

¹ACR-EULAR classification criteria can support early diagnosis. ²The treatment target is clinical remission according to ACR-EULAR definition or, if remission is unlikely to be achievable, at least low disease activity; the target should be reached after 6 months, but therapy should be adapted or changed if no sufficient improvement is seen after 3 months. ³MTX should be part of the first treatment strategy, while combination therapy of csDMARDs is not preferred by the Task Force, starting with MTX does not exclude its use in combination with other csDMARDs. ⁴TNF-inhibitors (adalimumab, certolizumab, etanercept, golimumab, infliximab, or respective well-studied and EMA/FDA approved biosimilars) abatacept, IL6-inhibitors, or rituximab (under certain conditions); in patients who cannot use csDMARD as comedication, IL6-inhibitors and tsDMARDs have some advantages. ⁵Current practice would be to start with a bDMARD (in combination

with MTX or another csDMARD) because of the long-term experience compared with tsDMARDs (JAK-inhibitors). ⁶The most frequently used combination comprises MTX, SSZ and hydroxychloroquine. ⁷ Efficacy and safety of bDMARDs after JAK-inhibitor failure is unknown; also, efficacy and safety of an IL-6 pathway inhibitor after another one has failed is currently unknown. ⁸ Efficacy and safety of a JAK-inhibitor after insufficient response to a previous JAK-inhibitor is unknown.

Prognostic unfavourable factors: RF/ACPA, especially at high levels; very high disease activity; early joint damage.

MTX, Methotrexate; SSZ, sulfasalazine; CI, contraindication; csDMARD, conventional synthetic Disease-Modifying Antirheumatic Drug; bDMARD, biological DMARD; tsDMARD, targeted synthetic DMARD; GC, glucocorticoids; TNF, Tumour Necrosis Factor; IL-6, interleukin 6; JAK, janus kinase.

Figure 11a. Prediction model of rapid radiographic progression (RPP) at one year generated from the ASPIRE early RA study (Adapted from Vastesaeger et al. 2009). The numbers in each cell represent the patients who had RRP as a percentage of all patients who had the same baseline characteristics and receive specific treatment. Blue (0-9%), green (10-19%), yellow (20-29%), orange (30-39%), red (40-100%)/ CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IFX, infliximab; MTX, methotrexate; RF, rheumatoid factor; SJC, swollen joint count).

Figure 11b. Performance on the different matrices with the ESPOIR patients who initially received methotrexate or leflunomide by ROC curve analyses (Granger et al, 2016). Data are area under the ROC curve (95% CIs). AUC, area under the ROC curve; CRP, C reactive protein; ROC, receiver operating characteristic

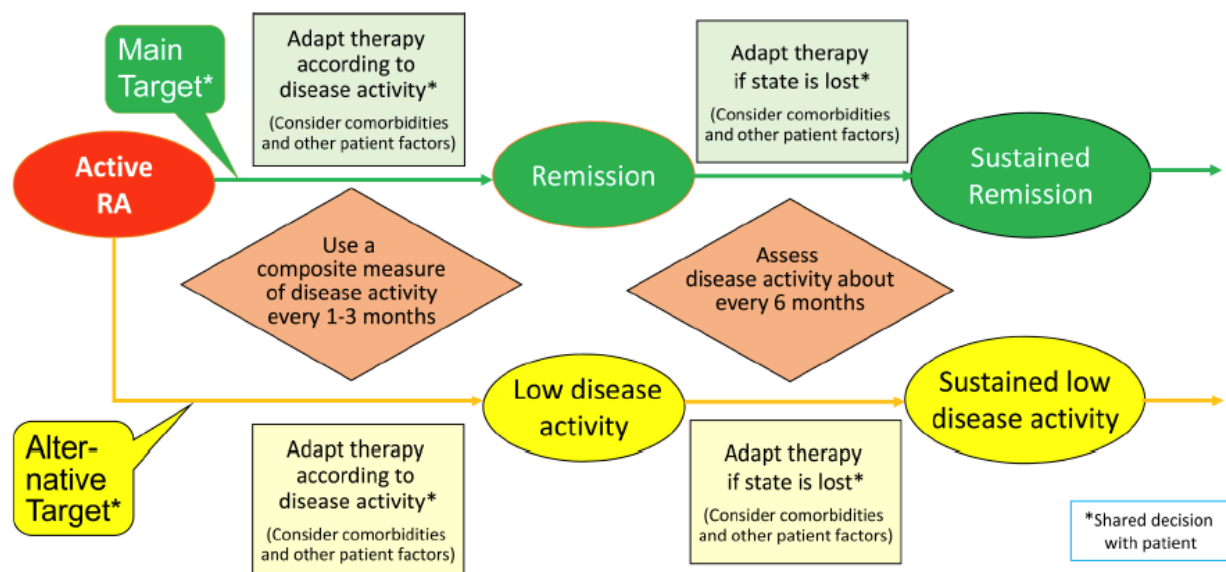

- *Monitoring should be frequent in active disease (every 1-3 months); if there is no improvement by at most 3 months after the start of treatment or the target has not been reached by 6 months, therapy should be adjusted.* This means that monitoring should be performed as frequently as disease activity necessitates, namely more frequently (such as 1-3 months) with active disease and less frequently (such as every 6-12 months) once the treatment target has been stabilised (**Figure 12**). EULAR advocates the use of composite measures of disease activity (**Table 1**), which include formal joint counts and the application of the ACR-EULAR criteria for remission (Felson et al, 2011). Further, this item clearly specifies that the treatment target (remission or at least low disease activity) should be attained within 6 months and not necessarily within 3 months; the 3-month time point relates solely to assessing improvement, meaning reduction of disease activity from a high to at least a moderate state by composite measures. If there is no improvement in disease activity (such as persistence of high disease activity) after 3 months, and provided that therapy has already been adjusted to maximise treatment effect, the ongoing therapy is usually unlikely to lead to the treatment goal in many additional patients even by 1 year and should be modified (Aletaha et al, 2007). Maximisation of treatment effects includes reaching an optimal MTX dose within a few weeks and maintaining the maximal dose (25-30 mg weekly) for at least 8 weeks. If improvement is achieved at 3 months, it must be borne in mind that maximal efficacy will not be seen before 6 months in many patients with most treatment strategies.

This is true for all types of therapies, including most biological agents. A similar approach should be made if the treatment target (remission or low disease activity) is not attained at 6 months.

Of note, individual patients may be well on their way to reaching the targets of low disease activity or remission at 6 months and might just take slightly more time to attain this desired state. Therefore the change in disease activity from treatment start to the 6-month time point will have to be taken into account when making final treatment decisions in the individual patients (Smolen et al, 2014*).

Figure 12. Algorithm of monitoring and treating RA to target according to the disease activity (Smolen et al, 2016). Adaptation of therapy should be usually done by performing control examinations with appropriate frequency and using composite disease activity measures that comprise joint counts, but should take comorbidities and other patient factors into account. Setting the target as well start and adaptation of therapy should be done as a shared decision with the patient.

MTX should be part of the first treatment strategy (Figure 10, phase I). Many systematic literature reviews reported that MTX is a highly effective agent both as monotherapy and in combination with glucocorticoids, other cs DMARDs and bDMARDs, and thus continues to serve as an anchor drug in RA (Pincus et al, 2003). As monotherapy with or without glucocorticoids, it is effective in DMARD-naïve patients and leads to low disease activity states or 70% improvement rates according to the criteria of the ACR (which corresponds to nearly a state of low disease activity (Aletaha et al, 2008)) in about 25-50% of patients with early RA within 6-12 months (Breedveld et al, 2006). The EULAR recommendations also insist on the importance of dose optimisation, optimal use of folic acid, and recognition that the maximum effect of MTX is attained only after 4-6 months. In this respect, the optimal dose (25-30 mg a week with folate substitution) should be maintained for at least 8 weeks as an important aspect on the way to ultimate treatment success.

- In patients with a contraindication to MTX (or early intolerance), leflunomide or sulfasalazine should be considered as part of the (first) treatment strategy (Figure 10, phase I). The term “early” has been added

to “intolerance” to indicate the Task Force’s view that early intolerance to MTX should be viewed as a contraindication and not as a failure of the 1st treatment strategy.

- ➡ *Low-dose glucocorticoids should be considered as part of the initial treatment strategy (in combination with one or more csDMARDs) for up to 6 months, but should be tapered as rapidly clinically feasible.* Many glucocorticoid treatment strategies exist, such as application of oral low- or intermediate-dos, of a single intramuscular injection or a single intravenous application, the latter two approaches usually having lower cumulative doses. Although the efficacy of GCs is well recognized, and although most studies on their toxicity are of low quality and short duration, the EULAR taskforce felt glucocorticoids toxicity, particularly in the intermediate to long term, should not be disregarded and thus glucocorticoids should be used with caution and preferably for only short periods of time as “bridging therapy”, while waiting for a DMARD to reach full effect. The modalities of glucocorticoids management will be detailed in **In-Depth Discussion 2**.
- ➡ *If the treatment target is not achieved with the first DMARD strategy, in the absence of poor prognostic factors, change to another csDMARD strategy should be considered; when poor prognostic factors are present, addition of a bDMARD should be considered.* Of note, recommendations state that MTX should be part of the first treatment strategy; the term “strategy” inherently does not exclude combinations of csDMARDs. The most often used combination (which was thought for a long time to be more efficacious than MTX monotherapy) is MTX plus sulfasalazine plus hydroxychloroquine. However, the 2016 EULAR Task Force does not primarily recommend it. Indeed, several recent trials (tREACH, CareRA) revealed that MTX monotherapy in combination with glucocorticoids is not less efficacious than combination of csDMARDs plus glucocorticoids, but has less safety issues (Verschueren et al, 2015; de Jong et al, 2014). In patients with low risk of progressive disease, adding a csDMARD when MTX has not sufficiently improved disease activity is a possible therapeutic option, although switching the csDMARD is just as good an option (Goekoop-Ruiterman YP et al, 2005).

When the first treatment cycle fails, EULAR recommends stratification for predictors of severe disease (high disease activity despite the previous therapy, autoantibodies – ACPA or/and RF- especially at high titres, and early joint damage on radiography. Patients with these risk factors should receive a biological DMARD, whereas those without should receive another csDMARD again in combination with glucocorticoids (**Figure 10, phase II**).

- ➡ *In patients responding insufficiently to MTX and/or other csDMARD strategies, with or without glucocorticoids, bDMARDs [TNF inhibitors (adalimumab, certolizumab, etanercept, golimumab, infliximab and EMA/FDA approved biosimilars), abatacept or tocilizumab, and under certain circumstances, rituximab] or a tsDMARD (JAK-inhibitor) should be commenced with MTX. However, current practice would be to start with a bDMARD because of the long-term experience compared with tsDMARDs.*

The Task Force reiterated that bDMARDs should primarily be started when patients did not achieve the therapeutic target after treatment with csDMARDs for 6 months (or had no improvement at 3 months). Concerning bDMARDs, solid data from registries, metaanalyses and head-to-head studies suggest that they seem to have similar clinical and structural efficacy (Nam et al, 2014; Schoels et al, 2012, Weinblatt et al, 2013), as well as a similar safety profile (Morel et al, 2013; Horak et al, 2013; Gottenberg et al, 2010; Godot et al, 2013; Weinblatt et al, 2013). Hence, the EULAR Task Force decided no preference of one over another bDMARD should be expressed. However, the 2013 Task Force recognized that there was still more experience with other bDMARDs, and that more safety data from registries would be desirable for the newer bDMARDs (Smolen et al, 2014*).

It is also important to note that the Task Force intentionally added “under certain circumstances rituximab”. While rituximab is approved for use after patients have responded insufficiently to TNF blockers, the Committee acknowledged that, in the presence of certain contraindications for other agents (such as a recent history of lymphoma, latent tuberculosis with contraindications to the use of chemoprophylaxis, living in a TB-endemic region, or a previous history of demyelinating disease) rituximab may be considered as first-line biological agent (Smolen et al, 2014*). Some rheumatologists also prioritise this drug in patients with a recent history of malignancy, because there are no indications that rituximab use is associated with the occurrence of cancers (Buch et al, 2011). Furthermore, rituximab is the least expensive agent at present.

Although the tofacitinib database has been enlarged by long-term extension studies which did not reveal new safety issues since 2013, and although baricitinib has completed phase 3 trials and revealed significant efficacy (also compared with a TNF-inhibitor) without new safety issues, the 2016 Task Force felt necessary to reiterate that current practice would be to start with a bDMARD because of the long-term experience compared with tsDMARDs.

- *bDMARDs and tsDMARDs should be combined with a csDMARD; in patients who cannot use csDMARDs as comedication, IL-6 pathway inhibitors and tsDMARDs may have some advantages compared to other bDMARDs.*

There is compelling evidence that all bDMARDs, including tocilizumab, convey better clinical functional and structural outcomes in combination with csDMARDs, especially MTX. This may not be the case for JAK inhibitors, although baricitinib in combination with MTX had better structural, though not better clinical and functional outcomes than as monotherapy (Taylor et al, 2015).

- *If a bDMARD or tsDMARD has failed, treatment with another bDMARD should be considered; if one TNF inhibitor therapy has failed, patients may receive another TNF inhibitor or an agent with another mode of action.*

The second part of this recommendation expresses the conclusion of the Task Force that current evidence does not suggest any one agent to be better than another TNF inhibitor when active disease prevails despite initial treatment with a TNF blocker.

- ➡ *If a patient is in persistent remission after having tapered glucocorticoids, one can consider tapering bDMARDs, especially if this treatment is combined with a csDMARD.*

Achievement of low disease activity (LDA) or sustained remission raises the possibility of DMARD tapering, titration or/and discontinuation. Until quite recently, treatment was based on the paradigm of continuous treatment for a chronic and lifelong disease, with the underlying perception that drug-free remission is rare, and there is no rationale to change a winning “team” (Den Broeder et al, 2010). In addition, several publications have highlighted the risk of disease relapse in cases of DMARD cessation (O’Mahony R et al, 2010; Van Herwaarden et al, 2014), with the risk of subsequent secondary failure of the DMARD that was stopped. In the last decade, this point of view has changed. The first reason was that achievement of remission or LDA in increasing number of patients (Aga et al, 2015), raising the question of whether drug-free remission would be possible to achieve (Klarenbeek et al, 2010; Van Nies et al, 2015). In addition, with RA prognosis improving, it appeared that the risks or disadvantages of DMARD continuation, for example the risk of serious infections (Smolen et al, 2016, Singh et al, 2015) and costs, could exceed the risks of active RA. That is why the EULAR guidelines have included the tapering of RA therapies in the 2013 and 2016 recommendations (**Table 12**).

Practice points can be developed from these recommendations (Fautrel, 2015):

- bDMARD discontinuation/withdrawal in established RA patients who can achieve low disease activity (LDA)/remission is associated with a high risk of relapse, usually > 50% in the year following discontinuation (Fautrel, 2015). Relapses occur particularly in the first 6 months after treatment reduction and are associated with the presence of ACPA (Haschka et al, (RETRO study) 2016).
- bDMARD tapering – either dose reduction or injection spacing – can be proposed to any established RA patient in sustained remission or LDA, as no clear predictors of tapering success have been identified thus far (Fautrel et al, (STRASS trial), 2014).
- No difference among DMARDs has been demonstrated with regard to the risk of relapse after implementation of tapering or discontinuation strategy.
- DMARD tapering should be conducted in the following order: corticosteroids dose reduction when medium to high dose are used (up to complete discontinuation if feasible), bDMARD, and finally csDMARDs (see next EULAR recommendation below) and low-dose steroids.
- Careful patient monitoring needs to be maintained after implementation of a tapering strategy, according to tight-control and treat-to-target paradigms.

- For the maintenance of sustained remission or LDA in established RA patients, half-dose etanercept is reportedly similar to full dose (Van Vollenhoven et al, 2016).
- Progressive and disease-activity-driven tapering strategies should be preferred; in case of relapse, return to previous administration scheme usually enables the rapid control of increases in disease activity (Fautrel et al, (STRASS trial), 2014; Van Herwaarden et al, (DRESS trial), 2015).
- Risk of clinically relevant structural damage progression appears very low after the implementation of a disease-activity-driven DMARD tapering (Fautrel et al, (STRASS trial)).
- No relevant reduction in the risk of adverse events was observed with DMARD tapering, potentially due to the “dilution of the susceptible” phenomenon [or “survivor bias”; although the (dose-dependent) risk of serious infections seems to be maximal in the few months of the drug initiation (csDMARD or/and bDMARD), the more at-risk patients quit the treatment later] (Fautrel, 2015).
- bDMARD tapering strategies are associated with substantial reduction in costs ranging from 3000 to 6000 per patient per year, with no or limited loss in health benefits (QALY) (Fautrel et al, 2011; Fautrel, 2015).

Table 12: More evidence from literature supporting the possibilities of tapering in RA

- In established RA, the available data suggest that most patients flare upon withdrawal of a TNF inhibitor (Tanaka et al, 2010; Tanaka et al, 2013; Kavanaugh et al, 2013; Chatzidionysiou et al, 2012; Haschka et al, (RETRO study) 2016) and more profound and persistent responses increase the likelihood of maintenance of a good outcome with csDMARDs even after withdrawal of the bDMARD (Tanaka et al, 2010). In the PRESERVE trial, the time frame was at least 4 months (Smolen et al, 2013). However, for early RA, the data are somewhat contradictory. While the primary target in early RA clearly should be stringent remission (Smolen et al, 2010; Felson et al, 2011) most data on withdrawal of bDMARDs come from patients who are in sustained low disease activity.
- The OPTIMA trial showed that a 6-month induction regimen with adalimumab plus MTX soon after diagnosis may be sufficient to allow most patients to maintain low disease activity or remission after open label and even after double-blind withdrawal of the TNF inhibitor (Kavanaugh et al, 2012; Klarenbeek et al, 2011; Smolen et al, 2014); however, while similar findings on withdrawal of a TNF blocker were obtained in an open label fashion in the HIT HARD study (Detert et al, 2013), somewhat contradicting data were seen in the PRIZE trial, where dose reduction but not withdrawal of the biological agent was accompanied by maintenance of good outcome (Emery et al, 2013). Thus, only if further and more broadly confirmed can short-term inclusion of a biological agent in a first DMARD strategy become a true option. On the other hand, reduction of the TNF inhibitor dose after attainment of DAS28<2.6 in early RA allows excellent outcomes to be maintained (Emery et al, 2013), as also seen in established RA (Smolen et

al, 2013; Fautrel et al (STRASS trial), 2013).

- While most studies on dose reduction or withdrawal have been performed with TNF blockers, some data on other bDMARDs are emerging with similar overall results (Takeuchi et al (ORION study), 2013; Nampei et al, 2013; Batticciotto et al, 2013) but clearly more information is needed in this regard.
- Importantly, before bDMARDs are tapered, glucocorticoids should have been withdrawn in line with EULAR recommendations. Also of note, reinstitution of bDMARDs appears to allow the good outcome to be recaptured (Tanaka et al, 2010; Takeuchi et al, 2013; Brocq et al, 2009).

However, some points are still on the research agenda:

- The order and rapidity of DMARD reduction needs to be more fully investigated to identify optimal tapering strategies for all csDMARDs or bDMARDs.
- Soluble biomarkers and/or imaging markers are needed to identify patients most at risk of relapse after DMARD tapering.
- A reliable and consensual definition of flare is required to (1) disentangle loss of efficacy from transient and self-resolving flare, and to (2) organize the care of patients starting a tapering scheme, and be able to rapidly adapt a dose or an injection scheme in case of relapse.
- The potential impact of bDMARD tapering strategies on the development of antidrug antibodies deserves more attention.
- The cost-effectiveness ratio and the willingness to accept DMARD tapering strategies seem promising, but need additional investigation.

➞ *In case of sustained long-term remission, cautious reduction of csDMARD dose could be considered.*

This recommendation refers solely to those patients in whom glucocorticoids, if used, have already been stopped and/or who have attained and maintained the targeted therapeutic state on csDMARDs or those in whom bDMARDs have been successfully withdrawn (see above). It must be borne in mind that stopping csDMARDs in patients with established RA in remission is followed by flares in about 70% of patients, twice as frequently as maintaining therapy irrespective of regimen (ten Wolde et al, 1996; O'Mahony 2010). Therefore the focus of this item is on csDMARD reduction rather than cessation. On the other hand, drug-free remission may be an option in patients in whom therapy was initiated very early and who therefore also had achieved remission early in their disease course (van der Woude et al, 2011).

3. Future perspectives in the treatment of RA

Despite advances made over the past two decades, many open issues remain (*Smolen et al, 2016):

- It has been shown that RA is preceded by a pre-clinical phase, and that the immunologic conflict is anterior to the onset of the symptoms, with the presence in serum of ACPA many years before the first clinical sign (Klareskog et al, 2008; Schaeffer et al, 2012) (**Figure 13**). In this context, early treatment might be highly effective at preventing manifestation of rheumatoid arthritis if one could detect pre-rheumatoid arthritis or patients at increased risk. Future diagnostic approaches and therapeutics must address this issue (*Smolen et al, 2016).

Figure 13. The different stages of Rheumatoid Arthritis (adapted from Klareskog et al, 2008 and Schaeffer et al, 2012).

The current therapeutic approaches mainly focus on the clinical articular phase, with the goal of treatment-to-target and tight-control to prevent joint destruction, but also comorbidities such as atherosclerosis, lymphoma, osteoporosis or infections. The future approaches could focus on the pre-clinical articular phase, by preventing or treating the immunologic conflict or infraclinical inflammation, genetic modulation, modulation of the microenvironment and risk factors, etc.... This implies a better knowledge of RA's pathophysiology, and new diagnostic and therapeutic approaches in the future.

- It is not possible today to predict optimal responses or toxic risk for a given treatment. Molecular analyses have failed to answer this question (Ducreux et al, 2014; Ortea et al, 2012; Semerano et al, 2015) but works are ongoing to identify predictors to permit precision medicine approaches in rheumatology (*Smolen et al, 2016).

- Although stringent remission (or at least low disease activity) is today's therapeutic goal for RA, many patients do not reach this target or achieve it but remain dependent on medication, implying that new therapies are still needed (Smolen et al, 2016). New therapeutics are currently being developed on the basis of pathogenic insights and are being tested in early trials (**Table 13**).
- Many patients lose responsiveness over time. Immunogenicity and non-adherence are on explanation, but all the reasons are not totally clear and require better understanding (*Smolen et al, 2016).

Table 13. Potential future therapeutics for RA (adapted from *Smolen et al, 2016)

Biologics
▪ Cytokine inhibitors (human or humanised; e.g., targeting interleukin (IL)-6, IL-21, interferons, granulocyte-monocyte colony stimulating factors or its receptor)
▪ Cytokine-IgG fusion proteins (e.g., interleukin 4-IgG)
▪ Bi-specific antibodies
▪ miRNA targeting
Intracellular signal inhibitors
▪ Janus kinase inhibitors (e.g., baricitinib, filgotinib)
▪ Bruton's tyrosine kinase inhibitors
▪ PI3 kinase inhibitors
Cellular therapies
▪ Tolerogenic dendritic cell transfer
▪ Stem cell transfer
▪ T-regulatory-cell activation
Miscellaneous approaches
▪ Angiogenesis factors inhibition
▪ Osteoclast activation factors inhibition (anti-RANKL)
▪ Toll-Like receptors inhibitors
▪ PADI4 inhibitors
▪ Epigenetic modifiers (e.g., histone deacetylase inhibitors)

Appendix 1: Selection of the main clinical studies that have impacted RA care

Study name:

PROMPT study, adapted from Van Dongen H et coll. Arthritis Rheum 2007;56:1424-1432.

Objective

To demonstrate the ability of methotrexate to prevent the development of established RA in patients with early arthritis.

Population

110 patients with early undifferentiated arthritis, i.e., possible RA in ACR1958 criteria)

	MTX (n = 55)	Placebo (n = 55)
Age (yrs) / Female (%)	51 / 64	51 / 69
Disease duration (months)	10,2	8,6
SJC / DAS44	3 / 2.7	2 / 2.7
RF+ / ACPA+ (%)	37 / 22	36 / 27
VS / CRP (mg/L)	12 / 5	11 / 5
Erosive disease (%)	20	27

Design

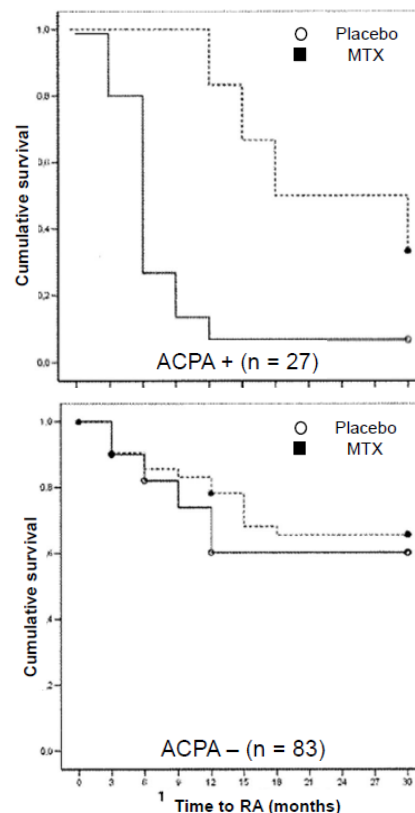

Randomized controlled trial vs placebo: Methotrexate 15 mg/week versus placebo

Endpoints: Satisfaction of ACR 1987 RA criteria, i.e., set up of a full RA presentation

Results:

MTX can prevent the development of established RA

The benefit is only obtained in ACPA+ patients

Study name:

GUEPARD trial, adapted from Rheumatology (Oxford). 2009 Nov;48(11):1429-34.

Objective

To assess the usefulness of a 3-month induction treatment with methotrexate + adalimumab in early RA patients.

Population

65 patients with early active RA: disease duration < 6 months AND DAS28 > 5.2

Mean DAS28 at baseline 6.2

RF+ 74% - ACPA+ 73% - erosive disease on X-rays 34%

Design

1-year randomized controlled trial with 2 arms:

MTX (0,3 mg/kg) monotherapy versus

MTX (0.3 mg/kg) + ADA (40 mg/wk) for 3 months, then MTX monotherapy if remission achieved.

Endpoints:

Disease activity at 12 months

Proportion of patients requiring TNF inhibitors at 12 months

Results:

No superiority of the MTX + ADA combination at 12 months in terms of disease activity and ACR responses.

The percentage of patients treated with TNF inhibitors at 12 months was similar between the 2 groups.

Study name:**BeSt trial**, adapted from:

- Goekoop-Ruiterman YP et al. Ann Intern Med 2007;146:406-15.
- Klarenbeek et al. 2011 ACR meeting and Ann Rheum Dis 2012;71:245-8.
- Markusse I et al. 2014 ACR meeting and Ann Intern Med. 2016 Apr 19;164(8):523-31.

Objective

To compare the efficacy in patients with early RA of 4 DAS-driven dynamic strategies based on “tight control” and “treat to target” paradigms.

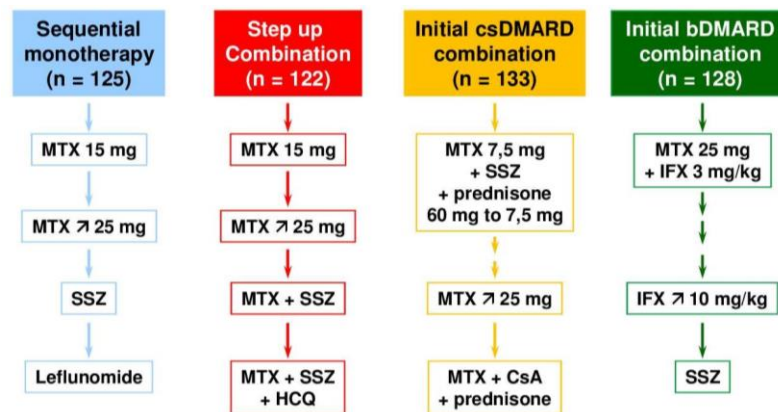

Population

508 people with active early RA (< 2 years), satisfying the 1987 ACR classification criteria, Active disease: swollen joint count ≥ 6 ; swollen joint count ≥ 6 ; ESR ≥ 28 or Patient global ≥ 20 , DAS28 assessment every 3 months and regular adjustment of DMARD according to the predefined strategy (see below) if DAS low disease activity (<2.4) was not achieved.

- DAS44 > 2,4 : next step regimen
- DAS44 $\leq 2,4$: same regimen
- DAS44 < 2,4 for more than 6 months: go back to previous step regimen

Design

Randomized controlled trial

Endpoints: Disease activity on DAS (44 joints),
Structural damage on X-rays (van der Heijde-modified Sharp score)

Results:

There were no differences in terms of RA disease activity during the 10-year follow-up (except during the 1st year of the trial).

Structural damage progression was higher during the 2 first years in the 2 initial monotherapy arms, but the difference did not persist afterwards.

Finally, the 10-year mortality was similar in the 4 arms and not different from the general population mortality (disappearance of the RA-associated cardiovascular mortality).

Study name:**SWEFOT trial**, adapted from

Van Vollenhoven RF et al. 2008 ACR meeting and Lancet 2009;374(9688):459-66.

Van Vollenhoven RF et al. 2009 ACR meeting and Lancet 2012;379(9827):1712-20. .

Objective

To compare csDMARD combination therapy (MTX + SSZ + HCQ) to MTX + TNF inhibitor (IFX) in the treatment of early RA patients with inadequate response to MTX.

Population

258 patients with early RA with inadequate response to MTX defined as DAS28 > 3.2 despite treatment with MTX 20 mg/week for 4 months.

Design

Randomized controlled trial with 2 arms: triple combination of csDMARD versus MTX + IFX.

Endpoints: ACR and EULAR responses at 1 and 2 years,
Strategy maintenance at 1 year,
Structural damage progression at 2 years.

Results:

At 1 year, the association MTX + IFX was superior to triple csDMARD combination in terms of ACR and EULAR responses (left figure), as well as maintenance rate (right figure).

At 2 years, there was no more difference for disease activity (left figure). However the structural damage progression was higher in the group with MTX + SSZ + HCQ triple association (right figure).

Study name

RACAT trial, adapted from O'Dell J et al. N Engl J Med. 2013;369(4):307-18.

Objective

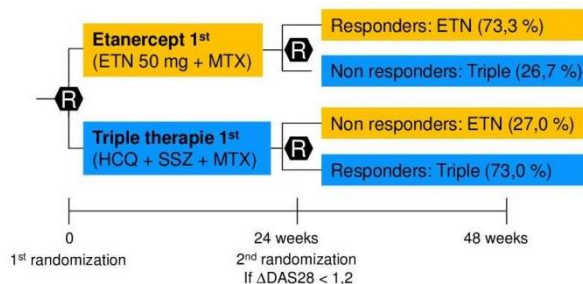

To assess the efficacy of Methotrexate + Etanercept compared to the triple association MTX + SSZ + HCQ in RA patients with inadequate response to MTX monotherapy.

Population

353 established RA patients with inadequate response to MTX, defined as DAS28 > 4.4 despite MTX 15-25 mg/wk for at least 12 months.

Design

1-year equivalence randomized controlled trial with 2 arms

Endpoints: DAS28 at 1 year;
Structural damage progression

Results:

The percentage of patients who did not respond adequately at 24 weeks was equivalent in the 2 randomization arms. Triple csDMARD association was not inferior to MTX + ETN in terms of disease activity, with a mean DAS28 decrease of 2.1 vs. 2.3 in the MTX + ETN group.

Of note, the Triple therapy was associated with a cost minimization of approximately 15,000 € per patient over 1 year, for a minimal loss of quality of life (- 0.017 quality-adjusted life year).

Study name:

ROC trial, adapted from Gottenberg JE, et al. 2013 and 2015 ACR meetings.

Objective

To compare 2 strategies in RA patients with inadequate response to a first TNF inhibitor: a second TNF inhibitor versus a biologic agent with another mode of action.

Population

300 established RA patients with inadequate response (i.e., DAS28 > 3.2) to a first TNF inhibitor
 Concomitant DMARD (77%) and steroids (2%) at stable doses
 Mean DAS28 at randomization: 5.1

Design

Randomized controlled trial with 2 arms:

2nd TNF inhibitor: ADA 57 – CZP 23 – ETN 53 – IFX 8

Other mode of action: ABA 33 – RTX – TCZ 70

Endpoints: EULAR response at 6 months

Results:

The rate of EULAR responses was higher in the group treated with another mode of action.

In the group treated with a 2nd TNF inhibitor, the response rate was higher in the patients for whom anti-drug antibodies were found before the discontinuation of the 1st TNF inhibitor.

In the group treated with another mode of action, the difference with TNF inhibitor was higher with tocilizumab.

Finally, the 2nd bDMARD was discontinued more frequently in the group treated with a 2nd TNF inhibitor (48 versus 27), for a lack of efficacy in more than 75% of the patients.

Study name:

PRESERVE trial, adapted from Smolen et al. Lancet 2013; 381(9870):918-29.

Objective

To demonstrate the superiority of etanercept maintenance at full or half-dose over etanercept discontinuation in patients with established RA having achieved sustained low disease activity with Methotrexate + Etanercept.

Design

Randomized controlled trial with 3 arms.

**Population**

604 patients with established RA: mean age 47 yrs, female 79 %,
 RA duration 6.9 yrs,
 mean DAS28 4.8 at baseline of the open labelled run-in period

Endpoints: Percentage of patients with persisting LDA or remission according to DAS28 or SDAI
 Structural damage progression

Results:

Etanercept maintenance (full and half dose combined) was superior to etanercept discontinuation in terms of LDA persistence and structural damage progression.

There was no statistical difference between the full dose or the half dose etanercept arms.

**Study name:**

DRESS trial, adapted from van Herwaarden N et al. BMJ 2015;350:h1389.

Objective

To demonstrate that a DAS-driven progressive tapering of TNF inhibitor (injection spacing) was non inferior to full regimen in established RA patients in sustained low disease activity with TNF inhibitors.

Population

180 patients with established RA in DAS28 low disease activity for more than 6 months

Either treated with adalimumab or etanercept

Concomitant csDMARD 60 to 80% - Steroids 5% (both at stable dose)

Mean DAS28 at inclusion 2.5

Design

18-month non inferiority randomized controlled trial with 2 arms:

Full dose regimen, i.e., ADA 40 mg eow or ETN 50 mg/wk

Progressive injection spacing if low disease activity was maintained (3 monthly assessments), according to a predefined protocol: ADA 40 mg / 3 wk, then 4 wk, then stop

or ETA 50 mg/2 wk, then 3 wks, then stop

In case of flare, TNF inhibitor were set back to previous step

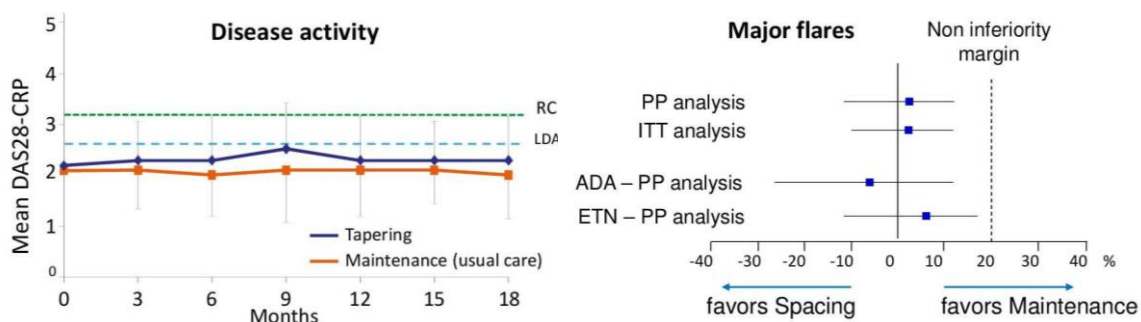

and intramuscular methylprednisolone injection was performed.

Endpoints: Flare, defined as DAS28 > 1.2 or Δ DAS28 > 0.6 AND DAS > 3.2
Major flare: flare persisting at 3 months despite dose escalation and IM prednisolone
Structural damage progression

Results:

At the end of the trial, 43% and 20% of the patients of the spacing arm were able to respectively space or discontinue their TNF inhibitor injections. The disease activity during the trial was not significantly different between the 2 groups (left figure).

Flares were more frequent in the spacing arm (88 of the 121 patients vs. 22 of 59 in the other arm). However, the frequency of major flare was equivalent in the 2 groups: 12 vs. 10, corresponding to a difference of 2 % (CI₉₅ : -12 ; 12), which was inside the equivalence margins (right figure)

Of importance, the equivalence with regards to major flares was counterbalanced by a significantly higher (but clinical meaningless) structural damage progression on X-rays (total Sharp score and joint space narrowing score).

Finally, the spacing strategy was associated with a cost minimization of approximately 9,000 € per patient over 18 months, for a minimal loss of quality of life (- 0.02 quality-adjusted life year).

Study name:

STRASS trial, adapted from Fautrel B et al. Ann Rheum Dis. 2016;75(1):59-67 and EULAR 2015 meeting.

Objective

To demonstrate that a DAS-driven progressive tapering of TNF inhibitor (injection spacing) was non inferior to full regimen in established RA patients in sustained remission with TNF inhibitors.

Population

138 patients with established RA in DAS28 remission for more than 6 months

Either treated with adalimumab or etanercept

Concomitant csDMARD 80% - Steroids 1% (both at stable dose)

Mean DAS28 at inclusion 1.8

Design

18-month non inferiority randomized controlled trial with 2 arms:

Full dose regimen, i.e., ADA 40 mg eow or ETN 50 mg/wk

Versus

Progressive injection spacing if remission was maintained (3 monthly assessments),

according to a predefined protocol: ADA 40 mg / 3 wk, then 4 wk, then 6 wk then stop
or ETA 50 mg/1.5 wk, then 2 wks, then 3 wk then stop

In case of flare, TNF inhibitor was set back to previous step (without steroid rescue).

Endpoints:

Weighted mean disease activity over the 18 months of follow-up

Relapse, defined as DAS28 > 2.6 AND Δ DAS28 > 0.6

Structural damage progression

Results:

The equivalence between the 2 arms was not demonstrated with a DAS28 standardized mean difference of 19% [95% CI, -5% to 46%] (equivalence margin of 20%). The relapse frequency was significantly higher in the spacing arm (left figure). However, the structural damage progression was similar between the 2 groups (Right figure).

Etanercept maintenance (full and half dose combined) was superior to etanercept discontinuation in terms of LDA persistence and structural damage progression.

There was no statistical difference between the full dose or the half dose etanercept arms.

The spacing strategy was associated with a cost minimization of approximately 8,000 € per patient over 18 months, for a not negligible loss of quality of life (- 0.2 quality-adjusted life year).

Appendix 2: management of antirheumatic drugs before and during pregnancy and lactation

Drug treatment during pregnancy may be required in order to control maternal disease which itself can be a threat for foetal well-being and pregnancy outcome. The risk of leaving active inflammatory rheumatoid arthritis of the mother untreated for 9 months must be weighed against any potential harm through drug exposure of the foetus (Ostensen et al, 2009). Adjustment of therapy in a patient planning a pregnancy aims to use medications that support disease control in the mother and are considered safe for the foetus. However, only a limited number of antirheumatic/ immunosuppressive drugs fulfil these requirements. Several sources of information are available:

- European Network of Teratology Information Services (ENTIS): <https://www.entis-org.eu/about>
- Organization of Teratology Information Specialists (OTIS): <http://mothertobaby.org/>

With the rapidly increasing number of medications available for the treatment of rheumatic disorders, knowledge on safety in pregnancy lags behind. Therefore, a EULAR Task Force has recently published points to consider for use of antirheumatic drugs before pregnancy and during pregnancy and lactation (Götestam Skorpen et al. 2016). Based on a systematic literature review and pregnancy exposure data from several registries, this multidisciplinary Task Force has established 4 overarching principles and 11 points to consider (**Table 16**). Compatibility with pregnancy and lactation was found for antimalarials, sulfasalazine, azathioprine, cyclosporine, tacrolimus, colchicine, intravenous immunoglobulin and glucocorticoids. Methotrexate (MTX), mycophenolate mofetil (MMF) and cyclophosphamide require discontinuation before conception due to proven teratogenicity. Insufficient documentation in regard to foetal safety implies the discontinuation of leflunomide, tofacitinib as well as abatacept, rituximab, belimumab, tocilizumab, ustekinumab and anakinra before a planned pregnancy. Of note, adverse outcomes other than congenital malformations were not consistently reported; this also applies to miscarriages. Rates of miscarriages may be imprecise since they depend on the time point at which a pregnant patient is included in a study. Only MTX and MMF have been consistently shown to increase the rate of miscarriages. Combination therapies with MTX have sometimes also increased the rate of miscarriages (Götestam Skorpen et al. 2016). **Table 17** sums up the conclusions of the Task Force for the management of NSAIDs, glucocorticoids, csDMARDs and tofacitinib, and **table 18** for the management of bDMARDs (Götestam Skorpen et al. 2016).

The biologics with the most pregnancy experience are Tumour Necrosis Factor inhibitors (TNFi) which have been in use for 15 years, including for indications outside rheumatology. For biologics approved <5 years ago, data on pregnancy and lactation are either sparse or completely absent. Hence, among biologics TNFi are best studied and appear reasonably safe with first and second trimester use (**table 18**). As they have a transplacental passage, TNFi use should be avoided, if possible, during the third trimester, because they

increase the infectious risk of the newborn during the first weeks of life (depending on the half-life of the molecule). Thus vaccination of the newborn with live attenuated vaccines should be postponed (in accordance with the paediatrician) if the TNFi has not been stopped during the last months of pregnancy. The difference in placental transfer related to molecule structure and half-life needs to be taken into account when selecting a TNFi for women of fertile age. Etanercept and certolizumab may be considered for use throughout pregnancy due to low rate of transplacental passage (**point 6, table 16**). Biologics are derivatives of IgG, and differ in structure, half-life and placental passage. The half-life ranges from 9 days to 23 days in complete IgG1 monoclonal antibodies and between 4 days and 13 days in Fc-fusion proteins (etanercept, abatacept) (Suzuki et al. 2010). Active transport of biologics containing the Fc part of IgG1 is mediated by the foetal Fc receptor expressed in the placenta (Suzuki et al. 2010). Transfer is thought to be very low during organogenesis, but to increase steadily after week 13 throughout pregnancy. Treatment of the mother with IgG antibodies expressing high affinity to the foetal Fc receptor after gestational week 30 can lead to foetal/cord serum levels equal to or higher than maternal levels (Mahadevan et al. 2013). IgG has a prolonged half-life, up to 48 days in the newborn (Sarvas et al. 1993); they typically disappear from the child's serum within the first 6 months of life. Pregnancy exposures in any trimester might have the potential to impair organ function, alter the immune response or influence neurocognitive development in children. One of the limits pointed out by the Task Force is that many studies have a short follow-up time and show large gaps in reported outcomes (Götestam Skorpen et al. 2016). Another striking data from this work was the observation of great heterogeneity in regard to clinical practice among experts, especially on breast-feeding management in patients receiving DMARDs. Since 30–50% of pregnancies are unplanned, a major question is how to manage pregnancies that occur in women receiving therapy with teratogenic drugs. Some patients opt for immediate termination whereas others contemplate continuation of the pregnancy. Confirmation of pregnancy by a gynaecologist and determination of exact exposure dates for individual risk assessment and counselling are mandatory. A detailed ultrasound examination of the foetus should be offered to all patients who have an unintended pregnancy while taking a teratogenic drug. Macroscopic anomalies can be assessed by experienced foetal medicine specialists at the end of the first trimester and scans should be repeated at later stages of the second trimester. Other prenatal tests like amniocentesis or chorionic villous biopsy are usually not indicated after maternal drug exposure, but might be considered in patients with high risk of chromosomal problems or anomalies at ultrasound examination.

Table 16: The EULAR points to consider for use of antirheumatic drugs before pregnancy and during pregnancy and lactation (adapted from Götestam Skorpen et al. 2016).

<i>Overarching principles</i>	
A Family planning should be addressed in each patient of reproductive age and adjustment of therapy considered before a planned pregnancy.	
B Treatment of patients with rheumatic disease before/during pregnancy and lactation should aim to prevent or suppress disease activity in the mother and expose the foetus/child to no harm.	
C The risk of drug therapy for the child should be weighed against the risk that untreated maternal disease represents for the patient and the foetus or child.	
D The decision on drug therapy during pregnancy and lactation should be based on agreement between the internist/rheumatologist, gynaecologist/obstetrician and the patient, and including other healthcare providers when appropriate.	
<i>Points to consider for use of antirheumatic drugs in pregnancy*</i>	<i>Grade of recommendation†</i>
1 csDMARDs‡ proven compatible with pregnancy are hydroxychloroquine, chloroquine, sulfasalazine, azathioprine, cyclosporine, tacrolimus and colchicine. They should be continued in pregnancy for maintenance of remission or treatment of a disease flare.	B
2 csDMARDs‡ methotrexate, mycophenolate mofetil and cyclophosphamide are teratogenic and should be withdrawn before pregnancy.	B
3 Non-selective COX inhibitors (non-steroidal anti-inflammatory drugs, NSAIDs) and prednisone should be considered for use in pregnancy if needed to control active disease symptoms. NSAIDs should be restricted to the first and second trimesters.	B
4 In severe, refractory maternal disease during pregnancy methylprednisolone pulses, intravenous immunoglobulin or even second or third trimester use of cyclophosphamide should be considered.	D
5 csDMARDs‡, tsDMARDs§ and anti-inflammatory drugs with insufficient documentation concerning use in pregnancy should be avoided until further evidence is available. This applies to leflunomide, mepacrine, tofacitinib and selective COX II inhibitors.	B–D
6 Among bDMARDs¶ continuation of tumour necrosis factor (TNF) inhibitors during the first part of pregnancy should be considered. Etanercept and certolizumab may be considered for use throughout pregnancy due to low rate of transplacental passage.	B
7 bDMARDs¶ rituximab, anakinra, tocilizumab, abatacept, belimumab and ustekinumab have limited documentation on safe use in pregnancy and should be replaced before conception by other medication. They should be used during pregnancy only when no other pregnancy-compatible drug can effectively control maternal disease.	D
<i>Points to consider for use of antirheumatic drugs during lactation*</i>	<i>Grade of recommendation†</i>
1 csDMARDs‡ and anti-inflammatory drugs compatible with breast feeding should be considered for continuation during lactation provided the child does not have conditions that contraindicate it. This applies to hydroxychloroquine, chloroquine, sulfasalazine, azathioprine, cyclosporine, tacrolimus, colchicine, prednisone, immunoglobulin, non-selective COX inhibitors and celecoxib.	D
2 csDMARDs‡, tsDMARDs§ and anti-inflammatory drugs with no or limited data on breast feeding should be avoided in lactating women. This applies to methotrexate, mycophenolate mofetil, cyclophosphamide, leflunomide, tofacitinib and cyclooxygenase II inhibitors other than celecoxib.	D
3 Low transfer to breast milk has been shown for infliximab, adalimumab, etanercept and certolizumab. Continuation of TNF inhibitors should be considered compatible with breast feeding.	D
4 bDMARDs¶ with no data on breast feeding such as rituximab, anakinra, belimumab, ustekinumab, tocilizumab and abatacept should be avoided during lactation if other therapy is available to control the disease. Based on pharmacological properties of bDMARDs¶, lactation should not be discouraged when using these agents, if no other options are available.	D

*Level of evidence is given for each drug separately in the original article.; †A Category I evidence from meta-analysis of randomised controlled trials (1A) or from at least one randomised controlled trial (1B); B Category II evidence from at least one controlled study without randomisation (2A) or from at least one type of quasi-experimental study (2B), or extrapolated recommendations from category I evidence.; C Category III evidence from descriptive studies, such as comparative studies, correlation studies or case-control studies (3), or extrapolated recommendation from category I or II evidence.

D Category IV evidence from expert committee reports or opinions and/or clinical experience of respected authorities (4), or extrapolated recommendation from category II or III evidence.

‡Conventional synthetic DMARDs. §Targeted synthetic DMARDs. ¶Biologic DMARDs.

Table 17A: Consensus on statements and expert opinion on use of NSAIDs, csDMARDs and tofacitinib in clinical practice in pregnant and lactating patients (adapted from Götestam Skorpen et al, 2016)

Drug	Pregnancy			Breast feeding		
	Statement on compatibility of drug with pregnancy based on evidence	Percentage of agreement with statement	Expert opinion on use of drug in clinical practice*	Statement on compatibility of drug with breast feeding based on evidence	Percentage of agreement with statement	Expert opinion on use of drug during breast feeding†
Non-selective COX inhibitors (classical NSAIDs)	Current evidence indicates no increased rate of congenital malformations. Non-selective COX inhibitors can be continued during the first and second trimesters	92		Non-selective COX inhibitors are compatible with breast feeding	88	
Selective COX II inhibitors	Current evidence is insufficient. Selective COX II inhibitors should be avoided in pregnancy	100		Among COX II inhibitors only celecoxib has been sufficient studied; celecoxib is compatible with breast feeding, other COX II inhibitors should be avoided during lactation	94	
Prednisone	Current evidence indicates no increased rate of congenital malformations. Prednisolone/prednisone can be continued at the lowest effective dose throughout pregnancy (risk of gestational diabetes and infections)	100		Glucocorticoids are compatible with breast feeding	100	
Intra-articular/ Intramuscular glucocorticoids	Current evidence indicates no increased rate of congenital malformations. Can be given, when required, throughout pregnancy	100				
Intravenous glucocorticoids	Current evidence indicates no increased rate of congenital malformations. Can be given, when required, throughout pregnancy	100				
Fluorinated glucocorticoids	Current evidence indicates that fluorinated glucocorticoids should be used with caution because they are less metabolised by the placenta. They should only be used to treat foetal problems.	100				

Hydroxychloroquine	Current evidence indicates no increased rate of congenital malformations. Can be continued throughout pregnancy	100		Compatible with breast feeding	100	
Chloroquine	Current evidence indicates no increased rate of congenital malformations. Can be continued throughout pregnancy	100		Compatible with breast feeding	88	
Methotrexate	Current evidence indicates an increased rate of congenital malformations. In a planned pregnancy, MTX should be withdrawn 1-3 months before pregnancy‡. Need for contraception if patient under treatment	100		Only small amounts of MTX appear in breast milk, but data are limited, therefore MTX should be avoided in breast feeding	100	
Leflunomide	Current evidence is insufficient. In a planned pregnancy, a washout procedure should be completed before pregnancy¶. Leflunomide should be avoided in pregnancy (need for contraception if patient under treatment)	100		No data exist regarding leflunomide in breast milk, therefore it should be avoided in breast feeding	100	
Sulfasalazine	Current evidence indicates no increased rate of congenital malformations. Sulfasalazine can be continued at doses up to 2g/day with concomitant folate supplementation throughout pregnancy.	100		Compatible with breast feeding in the healthy, full-term infant	94	
Cyclosporine	Current evidence indicates no increased rate of congenital malformations. Cyclosporine can be continued throughout pregnancy at the lowest effective dose	100		Compatible with breast feeding	100	
Tofacitinib	Current evidence is insufficient. In a planned pregnancy, treatment with tofacitinib should be stopped 2 months before conception	100		No data exist regarding tofacitinib in breast milk, therefore tofacitinib should be avoided in breast feeding	100	

‡ In theory, MTX in women could be stopped one month before conception (one cycle). In men, MTX should be interrupted 3 months (duration of spermatogenesis cycle) before conception. It can also induce a reversible oligospermia. ¶ Cholestyramine 3x8g/day during 11 days.

*As an expert in the field.

I would recommend the drug in the same way as if the patient was not pregnant.

I would only recommend the drug if I feared at least moderate disease activity in its absence.

I would only recommend the drug if I feared at least severe disease activity in its absence.

I would never recommend the drug in pregnancy.

†As an expert in the field.

I would recommend the drug in the same way as if the patient did not breastfeed.

I would only recommend the drug if I feared at least moderate disease activity in its absence

I would only recommend the drug if I feared at least severe disease activity in its absence.

I would never recommend the drug while the woman was breast feeding.

Table 18A: Consensus on statements and expert opinion on use of biologic drugs in clinical practice in pregnant and lactating patients (adapted from Götestam Skorpen et al, 2016).

Drug	Pregnancy			Breast feeding		
	Statement on compatibility of drug with pregnancy based on evidence	Percentage of agreement with statement	Expert opinion on use of drug in clinical practice (%)*	Statement on compatibility of drug with breast feeding based on evidence	Percentage of agreement with statement	Expert opinion on breast feeding and medication (%)†
Infliximab	Current evidence indicates no increased rate of congenital malformations; infliximab can be continued up to gestational week 20; if indicated, it can be used throughout pregnancy‡	100		Infliximab is compatible with breast feeding	100	
Adalimumab	Current evidence indicates no increased rate of congenital malformations; infliximab can be continued up to gestational week 20; if indicated, it can be used throughout pregnancy‡	100		Adalimumab is compatible with breast feeding	100	
Golimumab	Current evidence does not indicate an increased rate of congenital malformations; because of limited evidence, alternative medications should be considered for treatment throughout pregnancy‡	100		Golimumab is compatible with breast feeding	94	
Etanercept	Current evidence indicates no increased rate of congenital malformations; infliximab can be continued up to gestational week 30-32; if indicated, it can be used throughout pregnancy‡	100		Etanercept is compatible with breast feeding	100	
Certolizumab	Current evidence indicates no increased rate of congenital malformations; certolizumab can be	100		Certolizumab is compatible with breast feeding	94	

	used throughout pregnancy [‡]					
Rituximab	Current evidence indicates no increased rate of congenital malformations; in exceptional cases it can be used in early gestation; with use at later stages of pregnancy clinicians should be aware of the risk of B cell depletion and other cytopenia in the neonate	100		No data exist regarding rituximab in breast milk, therefore rituximab should be avoided in breast feeding	80	
Abatacept	No statement can be made in regard to safety during pregnancy due to scarce documentation; treatment with abatacept is therefore best avoided	94		No data exist regarding abatacept in breast milk, therefore abatacept should be avoided in breast feeding	75	
Tocilizumab	No statement can be made in regard to safety during pregnancy due to scarce documentation; treatment with tocilizumab is therefore best avoided	100		No data exist regarding tocilizumab in breast milk, therefore tocilizumab should be avoided in breast feeding	69	
Anakinra	Current evidence does not indicate an increased rate of congenital malformations; anakinra can be used before and during pregnancy when there are no other well studied options available for treatment	100		No data exist regarding anakinra in breast milk, therefore anakinra should be avoided in breast feeding	88	

*As an expert in the field.

I would recommend the drug in the same way as if the patient was not pregnant.
I would only recommend the drug if I feared at least moderate disease activity in its absence.

I would only recommend the drug if I feared at least severe disease activity in its absence.

I would never recommend the drug in pregnancy.

†As an expert in the field.

I would recommend the drug in the same way as if the patient did not breastfeed.

I would only recommend the drug if I feared at least moderate disease activity in its absence.

I would only recommend the drug if I feared at least severe disease activity in its absence.

I would never recommend the drug while the woman was breast feeding

[‡] Owing to their transplacental passage, TNFi use should be avoided, if possible, during the third trimester, as they increase the infectious risk of the newborn during the first weeks of life (depending on the half-life of the molecule). Thus vaccination of the newborn with live attenuated vaccines should be postponed (in accordance with the paediatrician) if the TNFi has not been stopped during the last months of pregnancy. Etanercept and certolizumab may be considered for use throughout pregnancy due to low rate of transplacental passage

Appendix 3: Vaccination for patients with RA

Patients with RA are at higher risk of developing infections, owing to deregulation of the immune response against pathogens inherent to disease pathogenic mechanisms. The organ damage induced by disease activity additionally creates a “locus minor of resistance” that favours infections. DMARDs, particularly immunosuppressors and biological agents, might increase the risk of infections and at the same time impair vaccination response.

Data from individual analysis of different conventional synthetic and biological DMARDs indicate that the humoral response to vaccination can be decreased by DMARDs, mainly by biological agents, and the response depends on the type of antigen, the cell pathways that are required to mount the immune response and the mechanism of action of the specific drug. It is therefore advisable that patients are vaccinated before starting biological DMARDs. If this is not possible, vaccinations should probably be given in an ideal “window of opportunity”, difficult to define. There should be enough time from the previous drug administration, in order to minimise the effect of the drug on the immune system, and at the same time allow a minimum amount of time before the next administration to enable an adequate immune response to the vaccine. Considering rituximab as an example, vaccination should be performed at least 6 months after the previous course and 4 weeks before the next one.

The administration of live attenuated vaccines in immunosuppressed patients has a potential risk of severe infection by these pathogens (Table 14) and should be avoided (Van Assen et al. 2011).

Table 14. Live attenuated vaccines

• Measles
• Mumps
• Poliomyelitis (oral)
• Rubella
• VZV
• Typhoid fever (oral)
• Yellow fever
• Tuberculosis (BCG, bacilli Calmette-Guerin)
• Rotavirus

In spite of these concerns, small studies have reported vaccination with measles, mumps, rubella and varicella in immunosuppressed children without alarm signals (King et al, 1996; Levin et al, 2006). Clinical trials on herpes zoster vaccination in immunosuppressed populations are ongoing and interpretation of the results will shortly be of help.

In view of these arguments and the increased use of biological DMARDs in rheumatic diseases, recommendations for vaccination in autoimmune inflammatory rheumatic disease were developed by a EULAR Task Force and integrate the most recent update of ACR recommendations for the use of DMARDs in the treatment of RA (van Assen et al, 2011; Singh et al, 2012) (Table 15). Indeed, most of these recommendations can be directly applied to patients with RA. It is important to reiterate, however, that for many of these statements the level of evidence is low owing to the lack of appropriate studies.

Table 15: Grade of evidence according to EULAR recommendations for vaccination in adult patients with autoimmune inflammatory rheumatic diseases

Recommended vaccines	Grade of evidence
Influenza	Ib–III
23-Valent pneumococcal polysaccharide	Ib–III
Tetanus toxoid	II
Human papilloma virus	III
Herpes zoster	III–IV
Hepatitis A and/or B	II–III

At first it is advisable to verify compliance with the national vaccination plan and if not, to recommend the missed vaccinations when the diagnosis of RA is established. Specifically, previous vaccination against tetanus toxoid, influenza, *Streptococcus pneumoniae*, hepatitis A and B, *Haemophilus influenzae* B, *Neisseria meningitides*, rubella (women in childbearing age) and human papillomavirus should be checked at the first visit (van Assen et al, 2011). Owing to a hypothetical risk of disease flare, vaccines should preferentially be administered during stable disease, according to expert opinion.

The rationale for prescribing vaccines in immunosuppressed patients is based on their potential ability to decrease infections. Influenza vaccination reduces admissions and mortality for influenza/pneumonia in elderly patients with rheumatic diseases. Influenza vaccine is efficacious in patients receiving conventional synthetic DMARDs, infliximab, adalimumab and etanercept, while the response after rituximab exposure is decreased. This response was not adequately assessed in patients treated with abatacept, tocilizumab, certolizumab and golimumab (Chalmers et al, 1994; Nichol et al, 1998; Hak et al, 2002; Del Porto et al, 2006; Fomin et al, 2006; van Assen et al, 2011). For this reason, seasonal and pandemic flu vaccinations are regularly recommended in patients with RA independently of which DMARD the patient is receiving (Saag et al, 2008; van Assen et al, 2011; Singh et al, 2012).

Pneumococcal vaccination immune response can be slightly reduced in patients with RA, particularly if receiving MTX, TNFi, rituximab and abatacept (Kapetanovic et al, 2006; Tay et al, 2007; Gelinck et al, 2008; Bingham et al, 2010). Pneumococcal vaccine is therefore recommended before the initiation of synthetic DMARDs and before starting any biological agent (Saag et al, 2008; van Assen et al, 2011; Singh et al, 2012).

Tetanus toxoid vaccination is included in the global plan of vaccination for the general population and it is, consequently, also given to patients with RA. Although after 24 weeks of rituximab therapy the response to tetanus toxoid stimulus is adequate, the effective protection offered before this period of time is unknown, making it advisable to treat patients with RA with tetanus immunoglobulins whenever a wound occurs in an environment with a high risk of tetanus infection. This is also probably true for patients receiving abatacept treatment (van Assen et al, 2011).

Herpes virus vaccination is controversial. Patients with RA have an increased risk of herpes zoster infection and this risk is further increased by glucocorticoids, csDMARDs and TNFi. No studies are available but there are concerns related to primary varicella infection caused by the vaccine strain in immunosuppressed patients. Given the high risk of herpes zoster infection, EULAR suggests that this vaccine could be administered in selected patients, who are not severely immunosuppressed and are seropositive for varicella zoster antibodies (to protect them from primary varicella infection), but emphasises that these recommendations are not validated but are based on expert opinion and require further investigation (van Assen et al, 2011). In line with this ACR experts consider that herpes zoster vaccine can be given before starting conventional synthetic DMARDs but it is not recommended for patients receiving biological DMARDs (Singh et al, 2012).

Human papilloma virus vaccination is generally recommended in many countries for women under 25 years old but there are no data on the prevalence of the infection or the efficacy of the vaccination in patients with RA. Recently, the administration of bivalent HPV16/18 vaccine to patients with juvenile idiopathic arthritis induced immunisation in all patients, even if the titre of antibodies was lower than in healthy controls. Although a slight increase in the risk of cervix dysplasia or cancer has been described in women with systemic lupus erythematosus or with organ transplantation – for whom powerful immunosuppressive agents are used – , there were no significant differences in patients receiving MTX or TNFi and vaccination was well tolerated without an increase in disease activity (Heijstek et al, 2014). Therefore the ACR panel recommends recombinant human papilloma virus vaccination to all patients before starting synthetic/biological DMARDs or during this treatment (Singh et al, 2012).

Vaccination for A and/or B hepatitis is advised by EULAR for patients who are at increased risk of infection, whereas the ACR states that this should be given to all patients with RA starting or currently receiving synthetic or biological DMARDs (Saag et al, 2008; van Assen et al, 2011; Singh et al, 2012).

Bacillus Calmette-Guérin (BCG) vaccination has not been clearly proved to prevent tuberculosis in adults and as it contains attenuated mycobacteria there is an increased risk of inducing infection in immunosuppressed patients. Additionally, most cases of tuberculosis in patients with RA are due to reactivation of previous infections, which cannot be prevented by vaccination. Therefore, BCG is not recommended for adult patients with RA (van Assen et al, 2011).

Concerns about disease flare after vaccination, owing to a broad stimulation of the immune response mediated by adjuvants, has led experts to advocate that vaccination should be performed when the disease is inactive. On the other hand, there is no formal evidence suggesting that the safety or efficacy of a vaccine is decreased during active disease (van Assen et al, 2011). This hypothetical risk has been based on various case reports of onset or exacerbation of various rheumatic diseases—for example, RA after vaccination. Some authors have suggested that genetic predisposition (major histocompatibility complex class II HLA-DR4 and/or HLA-DR1) might be an important risk factor. The phenotype of HBV vaccination-induced RA is similar to the idiopathic form. Many of these cases started 1 day after vaccination up to 20 days after immunisation and while some had a self-limiting course, in others the disease evolved into established RA that required chronic DMARD therapy (Vautier and Carty, 1994; Gross et al, 1995; Treves et al, 1997; Pope et al, 1998). However, more recently, in a large population case–control study the vaccinations for influenza, tetanus, diphtheria, tick-borne encephalitis, hepatitis, polio and pneumococcus were not associated with an increased risk of developing RA, including in smokers or patients expressing HLA-DRB1 shared epitope alleles (Bengtsson et al, 2010). Similarly, a retrospective case–control analysis of patients receiving vaccination against B hepatitis, tetanus and influenza did not show a significant association between these vaccinations and RA onset (Ray et al, 2011).

Awareness of the importance of performing vaccination, especially in patients receiving biological therapies, is now high, at least in some countries, but this is in contrast with the effective degree of immunisation of these populations (Feuchtenberger et al, 2012). This highlights the importance of applying in clinical practice guidelines for vaccination, aiming at decreasing the risk of severe infections. Finally, it is clear that evidence from appropriate studies is still lacking for most of the proposed vaccines and further research is needed.

Summary points

- Treatment of RA patients should aim at the best care and must be based on a shared decision between the patient and the rheumatologist.
- RA incurs high individual, societal and medical costs, all of which should be considered in its management by the treating rheumatologist.
- When therapy needs to be adjusted, factors apart from disease activity, such as progression of structural damage, comorbidities and safety issues should be taken into account.
- Therapy with DMARDs should be started as soon as the diagnosis of RA is made. This implies to make an early diagnosis, and ACR-EULAR diagnostic criteria might be of help.
- Treatment should be aimed at reaching a target of sustained remission or low disease activity in every patient (through “treatment-to-target” and “tight-control”).
- Assessment of a patient with RA should include at least the 28-joint count, patient’s assessment of global health, HAQ, acute phase markers, RF, ACPA, X-ray pictures of the affected joints and in selected patients (e.g., early disease and in established disease for clarifying the existence of active inflammation) ultrasonography with power Doppler and/or magnetic resonance.
- Monitoring should be frequent in active disease (every 1-3 months); if there is no improvement by at most 3 months after the start of treatment or the target has not been reached by 6 months, therapy should be adjusted.
- Assessment of risk factors for several medical complications, including cardiovascular diseases, serious infection, cancer, fragility fractures and gastrointestinal haemorrhage, should comprise part of the assessment and approach to the patient.
- MTX should be part of the first treatment strategy. In patients with a contraindication to MTX (or early intolerance), leflunomide or sulfasalazine should be considered as part of the (first) treatment strategy.
- Low-dose glucocorticoids should be considered as part of the initial treatment strategy (in combination with one or more csDMARDs) for up to 6 months, but should be tapered as rapidly clinically feasible (“bridging therapy” concept).
- If the treatment target is not achieved with the first DMARD strategy, in the absence of poor prognostic factors, change to another csDMARD strategy should be considered; when poor prognostic factors are present, addition of a bDMARD should be considered.
- In patients responding insufficiently to MTX and/or other csDMARD strategies, with or without glucocorticoids, bDMARDs [TNF inhibitors (adalimumab, certolizumab, etanercept, golimumab, infliximab and EMA/FDA approved biosimilars), abatacept or tocilizumab, and under certain circumstances, rituximab] or a tsDMARD (JAK-inhibitor) should be commenced with MTX. However, current practice would be to start with a bDMARD because of the long-term experience compared with tsDMARDs.
- bDMARDs and tsDMARDs should be combined with a csDMARD; in patients who cannot use csDMARDs as comedication, IL-6 pathway inhibitors and tsDMARDs may have some advantages compared to other bDMARDs.

Summary points

- If a bDMARD or tsDMARD has failed, treatment with another bDMARD should be considered; if one TNF inhibitor therapy has failed, patients may receive another TNF inhibitor or an agent with another mode of action.
- If a patient is in persistent remission after having tapered glucocorticoids, one can consider tapering bDMARDs, especially if this treatment is combined with a csDMARD.
- In case of sustained long-term remission, cautious reduction of csDMARD dose could be considered.
- Patients with RA are at higher risk of infections, and vaccination should be performed according to guidelines.
- The management of antirheumatic drugs before and during pregnancy and breast feeding should be perfectly known by rheumatologists because many are contraindicated owing to their potential dramatic effects on the foetus.
- Rheumatologists are the specialists who should primarily care for RA patients, but allied health professionals have an important role in the treatment of patients with RA and should be involved throughout as required (In-Depth Discussion 1).
- Symptomatic treatments (analgesics, NSAIDs) might be of help punctually, and local non-pharmacological should not be disregarded (In-Depth Discussions 2 and 3).
- Education and inclusion of patients (together with their family) in decision-making are critical to optimal care of this chronic condition.

EULAR on-line course on Rheumatic Diseases

Treatment of rheumatoid arthritis

Bruno Fautrel, Stéphane Mitrovic, Peter Taylor

A previous version was co-authored by Peter Taylor, Elsa Vieira-Sousa, João Eurico Fonseca The rheumatology

IN-DEPTH DISCUSSION I

The Role of Health Professionals in the Treatment of Rheumatoid Arthritis

In RA, besides the rheumatologist and general practitioner, multidisciplinary team care is provided by specialist health professionals including the rheumatology nurse specialist, physiotherapist, podiatrist, and occupational therapist (Figure 1). The role of each health professional will vary according to the model of care, setting, level of specialist training and expertise. It will also vary according to the disease phase (Table 1). In some areas, roles may overlap and be complementary and in all professions, extended scope practice is rapidly developing.

Figure 1 – Multidisciplinary approach of health professional in the care of rheumatoid arthritis patients.

The rheumatology nurse specialist/practitioner

The role of the RNP is to enable patients to maintain their physical, psychological and social functioning thanks to patient-centred care. RNP-led programs underpin this and have been shown effective:

- at the time of diagnosis to:

- facilitate *will work along with the other health professionals, and EULAR has recently established recommendations for education people with inflammatory arthritis (Zangi et al, 2015)]*,
- help them facing fatigue, anxiety or any difficulties in social participation, either in domestic or occupational lives,
- develop preventive medicine actions such as immunization check or screening for osteoporosis, hypertension or other cardiovascular disorders like demonstrated in the COMEDRA trial (Dougados et al, 2015) and like established in the “2016 EULAR points to consider for reporting, screening for

and preventing selected comorbidities in chronic inflammatory rheumatic diseases” (Baillet et al, 2016),

- coordinate patient care within the hospital or between hospital and community care when several health providers are needed.
- disease announcement
- and alleviate anxiety and fear associated with such an important news;

- during the course of the disease, as frequently as needed, to:

- improve disease and treatment understanding and acceptance by the patients,
- reinforce patient adherence to RA care and coping skills through dedicated educational programs *[on this topic which will be further developed in **In-Depth Discussion 3** (www.eular-onlinecourse.org), the RNP care can be implemented by face-to-face meetings (individual or group), by phone or other connected devices, or through community-based user-led self-management programs. The RNP will also direct patients to written information, internet resources and books as well as local and national arthritis organisations.*

An important study was conducted more than 10 years ago in United Kingdom: the implementation of a nurse helpline, easily reachable by RA patients whenever needed, led to higher patient satisfaction and fewer consultation to the rheumatologist compared to usual care (Hewlett et al, 2005) (**Figure 2 A and B**).

Recently, a cost comparison study in a randomised control trial showed that patients with chronic inflammatory arthritis and low disease activity or in remission undergoing biological therapy can be monitored with a reduced resource use and at a lower annual cost by a nurse-led rheumatology clinic, based on person-centred care, with no difference in clinical outcomes, when compared to a rheumatologist-led clinic (Laarson I et al, 2015). This could free resources for more intensive monitoring of patients early in the disease or patients with high disease activity.

EULAR recommendations regarding the contribution of nurses to the care of inflammatory arthritis patients have been developed in 2012 (van Eijk-Hustings et al. 2012). A more recent work two years later showed that these recommendations had been disseminated among nurses, rheumatologists and patients across Europe and the USA, and that agreement with these recommendations were high (van Eijk-Hustings et al, 2014). However, application was lower and differed across regions, and the most common barriers for application of the recommendations were time constraints and unavailability of the service. This underlines the need for developing the means in the future in some regions (van Eijk-Hustings et al, 2014).

Figure 2-A. Patient's confidence and satisfaction in the system (adapted from Hewlett et al, 2005)**Figure 2-B. Hospital rheumatologist appointments over six years (adapted Hewlett et al, 2005)**

The physiotherapist

In the management of RA the physiotherapist will work closely with patients to set goal-orientated treatment plans aimed at optimising function and independence. In early disease, information and advice is provided on joint protection, management of flare, pacing and activity cycling, fatigue and pain relief (see In-Depth Discussion 3 (www.eular-onlinecourse.org), Interventions for pain management include ice, heat, hydrotherapy, electrotherapy and muscle strengthening exercise may be used to improve function, posture and mobility. Some physiotherapists will assess gait and prescribe insoles, walking aids and gait adaptations to improve function and mobility. In addition, relaxation/mind-body approaches such as Tai Chi, relaxation and stress management can be implemented by such health professional.

The occupational therapist

The role of the occupational therapist in the management of RA is to improve/maintain the patient's ability to perform activities of daily living. Comprehensive occupational therapy programmes include activities of daily living assessment and training, joint protection, splinting, pain and fatigue management, assistive devices and environmental modification, patient education, counselling and work and leisure rehabilitation and these are beneficial in the short term for improving functional ability in patients with moderate to severe RA (see In-

Depth Discussion 3 (www.eular-onlinecourse.org). Hand and wrist splints and hand exercises are commonly prescribed and relaxation/mind-body approaches such as Tai Chi, relaxation and stress management may be beneficial for some RA patients. The occupational therapist may also provide counselling, psychological support and use cognitive behavioural therapy approaches and group programmes to help support change so this may involve family and carers.

The podiatrist

Foot problems are common in patients with RA and the role of the podiatrist is to reduce pain, maintain/improve function and mobility, and to protect the skin and soft-tissues of the foot. Correct footwear and specialised insoles (orthoses) are prescribed to protect joints and alleviate symptoms (see In-Depth Discussion 3 (www.eular-onlinecourse.org)). Advice is provided on basic foot hygiene and self-management, joint protection and muscle strengthening exercises and palliative care is provided for painful nail and skin lesions. The podiatrist will provide specialist wound care management for patients with foot ulceration. In an extended role the podiatrists may administer intra-articular or soft-tissue injections and in the UK there are a growing number of surgically trained podiatrists able to undertake forefoot reconstruction procedures.

Other health professionals

Other health professionals within the multidisciplinary team include the dietician who can advise RA patients on aspects of weight management, dietary interventions and dietary supplements (see In-Depth Discussion 3 (www.eular-onlinecourse.org)). The pharmacist has a role educating patients about drug therapy and monitoring for drug interactions and side effects. Newer roles include pharmacist-led DMARD clinics in primary care and expert input in outpatient clinics in support of supplementary prescribes. With a greater understanding of the burden of pain and fatigue in RA, enhancing self-efficacy and achieving behavioural change are the key treatment challenges. These concepts are central to cognitive behavioural therapy and more recently the clinical psychologist has become an increasingly valuable member of the team.

In conclusion

Optimal RA care needs to associate both physician and health professional care in a comprehensive and holistic care. For some authors, a patient annual (or every-other-year) review could be the best way to achieve this goal.

Table 1: Health care circuit for patients with rheumatoid arthritis (RA)

Health professional	Installation stage “pre-RA” or EUA*	Early stage Early RA	Established stage Established RA	Advanced stage Advanced RA
General Practitioner (GP)	Role: evocation of the diagnosis in front of: - ≥ 2 swollen joints - Morning stiffness > 30 min - Positive squeeze-test Action: - Prescription of paraclinical examinations (biology, X-rays) - Orientation to the rheumatologist - Symptomatic treatment: analgesics, NSAIDS	Role: following of the prescription of the rheumatologist, initiation of the collaboration with the rheumatologist (shared follow-up) Action: according to the severity of RA and the country's health system organisation, initiation of the social full medical care	Role: continuation of the collaboration with the rheumatologist (shared follow-up) Action: - Treatment tolerance monitoring - If necessary, renewal of medical prescription between two consultations with the rheumatologist - Prevention and shared management of comorbidities (vaccinations, cardiovascular evaluation)	
Rheumatologist	Role: confirmation of the diagnosis Action: - Diagnosis established on clinical features, biology, X-rays +/- echography - Symptomatic treatment : analgesics, NSAIDS, even oral steroids according to the inflammatory activity	Role: Initiation of therapy, sustained follow-up to evaluate efficacy and tolerance of the treatments Action: - Diagnosis announcement - Explication of RA issues - Establishing the objectives: low disease activity at 3 months, remission at 6 months - Initiation of csDMARD (MTX or other, according to tolerance and CI) - Treatment tolerance monitoring In practice: - Appointment every 3 months (+/- appointment 1 month after treatment initiation) - X-rays at 6 months, then every year	Role: Disease and treatment evaluation Action: - Disease activity evaluation through a composite index and biology - Articular deterioration evaluation through conventional X-rays - Evaluation and prevention of handicap - Treatment adaptation (step up or down) according to disease activity - If necessary, prescription of a bDMARD (private practice-hospital link) - Treatment tolerance monitoring In practice: - Appointments every 6 months (closer if RA not controlled) - X-rays every 1 to 2 years - Comorbidities management (in collaboration with the GP)	Role: Disease evaluation, of its consequences and treatments Action : - Disease activity evaluation, through a composite index and biology - Articular deterioration evaluation through conventional X-rays - Handicap evaluation and adaptation - Treatment adaptation (step up or down) according to disease activity - Treatment tolerance monitoring In practice: - Appointments every 6 to 12 months (according to disease activity) - X-rays every (1 to) 2 years - Establishment of social help for disability (according to the country's health system)

	- Proposition to participate to a therapeutic educational program	- If necessary, discussion of surgical procedures (correction or others)
Rheumatology nurse specialist/practitioner (RNP)	Role: Educational diagnosis Action: Therapeutic educational program (disease; treatments; biotherapies)	
Physiotherapist	Role: Advice on physical activity management Action: to define with each patient	Role: Handicap prevention, maintenance of physical activity Action : Maintenance of joint mobility and muscular trophicity
Occupational therapist	Role: Evaluation within the framework of a therapeutic educational program Action: to define with each patient, orthoses if necessary	Role: Evaluation of technical needs Action: technical assistance, aides techniques, orthoses making
Psychologist	Role: support and coaching Action : to define with each patient	
Pharmacist	Role: Reinforcement of medical drug information Action: Explication of daily drug medicine, information about alert signals, reinsurance	
Social worker	Role: Response to possible social questions Action: to define with each patient	Role: Evaluation of handicap and social help needs Action: according to each country's health system organisation
Occupational Medical Doctor	Role: Job maintenance help Action: Assessment of functional abilities according to the job position constraints, adaptation of the working conditions if necessary	
Patient associations	Role: Information and orientation of the patient Action: Organisation of meetings/ information sessions, development of information support, integration to therapeutic educational programs	

RA, Rheumatoid Arthritis; NSAIDS, non-steroidal anti-inflammatory drugs; DMARD, Disease-Modifying Anti-Rheumatologic Drug; csDMARD, conventional synthetic DMARD; bDMARD, biological DMARD; MTX, methotrexate; CI, contraindication; GP, General Practitioner;

*EUA, early undifferentiated arthritis

IN-DEPTH DISCUSSION II

Analgesics, NSAIDs, Coxibs and glucocorticoids in the treatment of RA

Introduction

Pain in patients with rheumatoid arthritis (RA) can have several pathophysiological mechanisms, for example inflammation and secondary osteoarthritis (nociceptive pain), secondary fibromyalgia (non-nociceptive pain due to sensitisation), and compression neuropathy (neuropathic pain, as in carpal tunnel syndrome). In addition, the experience of pain is influenced by socio-psychological factors. The approach of rheumatic pain involves evaluation of mechanisms for the optimal choice of (combinations of) pharmacological and non-pharmacological treatments (Fitzcharles, Almahrezi et al. 2005). This in-depth discussion will first focus on the use of analgesics and non-steroidal anti-inflammatory drugs (NSAID) including cyclooxygenase-2 (COX-2) inhibitors (Coxibs) as adjuvant in the treatment of nociceptive pain in RA. Then, a section will be dedicated to the (often controversial) glucocorticoids use in RA, specially emphasizing the now consensual concept of “bridging therapy”.

1. Analgesics

From the perspective of safety and cost, the American College of Rheumatology recommends that acetaminophen (also known as paracetamol) be tried first as adjuvant treatment for pain in RA, although most patients rate the effectiveness of NSAIDs higher (Lee et al. 1975; Wolfe et al. 2000; Wienecke and Gotzsche 2004). In the EULAR recommendations for the management of early arthritis, it is stated that symptomatic patients presenting with early arthritis should be treated with NSAIDs after careful evaluation of gastrointestinal, renal, and cardiovascular status (Combe et al. 2007). If the effect of either acetaminophen or NSAIDs alone is insufficient, these drugs can be combined (see below). Alternatively, the weak opioid tramadol (Lee et al. 2006) can be added to acetaminophen. Absorption and the analgesic effect of acetaminophen are enhanced if acetaminophen is combined with caffeine, e.g. as combination drug (Renner et al. 2007). Opioid analgesics have additive effects to acetaminophen, since their mode of action is different. Adverse effects, such as nausea and drowsiness, can limit their use; progressive dose increase may facilitate their tolerance.

Chronic use of acetaminophen is not perfectly safe; it could be associated with a significantly increased risk for major cardiovascular events, gastro-intestinal events such as dyspepsia and chronic renal failure (Forel et al. 2001; Garcia Rodriguez and Hernandez-Diaz 2001; Abramson 2002; Rahme et al. 2002; Chan et al. 2006). These adverse effects resemble those of NSAIDs. Acetaminophen indeed seems to have weak COX inhibiting properties in specific pathophysiological conditions (Abramson 2002). However, there might also be confounding bias because patients with more severe disease (who are more prone to cardiovascular and renal complications because of the uncontrolled disease) usually take more analgesics. Furthermore, acetaminophen might not be as safe during pregnancy as previously thought, because it has been reported that foetal exposure might increase the risk of cryptorchidism (Mazaud-Guittot S et al. 2013) or autism (Liew et al. 2015).

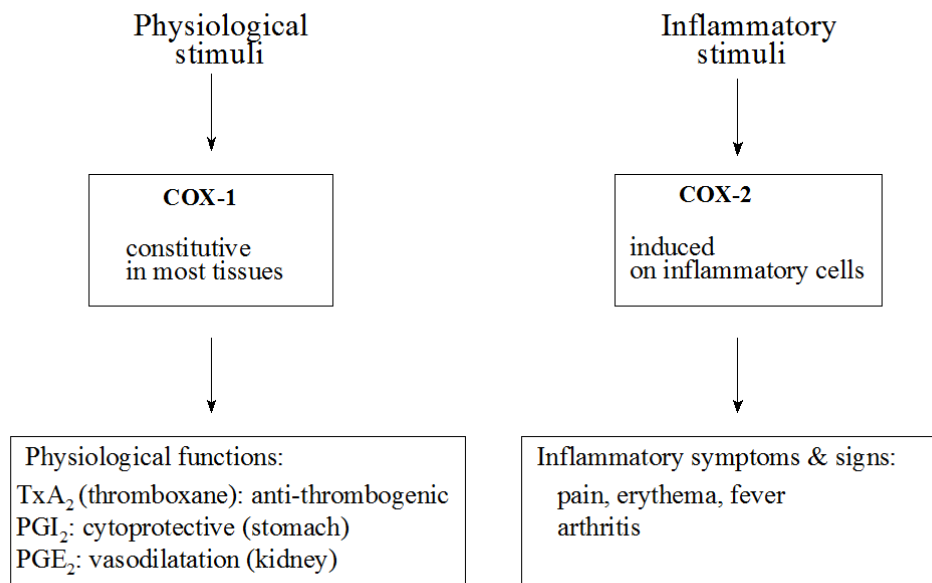

2. Non-steroidal anti-inflammatory drugs (NSAIDs) and Coxibs

2.1-NSAIDs mode of action

NSAIDs inhibit prostaglandin synthesis by inhibiting the enzyme COX which converts the precursor molecule arachidonic acid into various prostaglandins. Prostaglandins (PG) are ubiquitous locally synthesized mediators of inflammation. However, this effect is not as straightforward as it seems. Certain prostaglandins, such as PGE₂ and PGI₂ have not only pro-inflammatory but also anti-inflammatory properties (and numerous physiological functions). Non-acetylated salicylates, such as sodium salicylate, are about 100 times less effective than the acetylated salicylate aspirin in inhibiting COX, yet they are about as effective clinically in suppressing joint inflammation (Furst 1994). Aspirin, at doses sufficient to inhibit COX, inhibits platelet aggregation as expected but does not suppress inflammation: the doses needed to achieve anti-inflammatory effects are substantially higher ($\geq 1\text{g}$). Furthermore, NSAID also have other modes of action (Table 1), (Furst 1994). For most NSAID, both inhibition of COX and inhibition of neutrophil functions seem to play an important role in their anti-inflammatory properties. There are at least two isoenzymes: COX-1 and COX-2. COX-1 is a constitutive enzyme and it is present in most tissues. It has a role predominantly in physiological functions (Figure 1). Whatever the molecule, the delay of action is short, between 15 and 30 minutes, which makes oral administration as quickly efficacious as parenteral administration. The tolerance, especially the risk of digestive ulcer, is not influenced by the route of administration.

Table 1: Modes of action of NSAIDs

• Inhibition of prostaglandin synthesis (COX-mediated)
• Inhibition of leukotriene synthesis (lipoxygenase mediated)
• Inhibition of formation of toxic oxygen radicals from stimulated neutrophils
• Inhibition of lysosomal enzyme release
• Inhibition of neutrophil aggregation / adhesion / chemotaxis
• Altered T-lymphocyte function by inhibiting rheumatoid factor production (in vitro)
• Inhibited cartilage metabolism: impaired proteoglycan synthesis (in vitro)
• Cell membrane functions and signal transduction:
• Inhibited enzyme activity: NADPH oxidase, phospholipase C
• Inhibited transmembrane anion transport (erythrocytes, renal tubules)
• Uncoupling of oxidative phosphorylation
• Inhibited uptake of arachidonate
• Central analgesia

Figure 1: Outline of the COX-1 / COX-2-concept

According to this concept, inhibition of COX-1 causes predominantly side-effects and inhibition of COX-2 anti-inflammatory effects. For critical points that can be raised on this concept, see text and Table 3

COX-2 is present especially in inflammatory cells if induced by pathological, inflammatory stimuli, such as the cytokine interleukin 1. It has been hypothesized that inhibition of COX-1 results predominantly in gastro-intestinal side effects and that inhibition of COX-2 leads to inhibition of inflammation. On the basis of this hypothesis, COX-2 selective NSAIDs have been developed: the Coxibs. However, some critical points regarding the COX-2/COX-1 concept can be raised (Table 3).

Table 3: Items of discussion on the COX-1 / COX-2 concept

- The COX-1/COX-2 ratio for each individual NSAIDs depends on the laboratory model used
- Inhibition of COX is only one mode of action of NSAIDs, so the COX-1/COX-2 ratio is only one (albeit important) aspect of NSAIDs
- Clinical efficacy and superiority regarding side-effects over “old” NSAIDs has to be proven for each individual COX-2 selective NSAID
- There is probably no strict separation between the effects of the COX-1 and COX-2 isoenzymes
- There are probably more COX-isoenzymes than just two

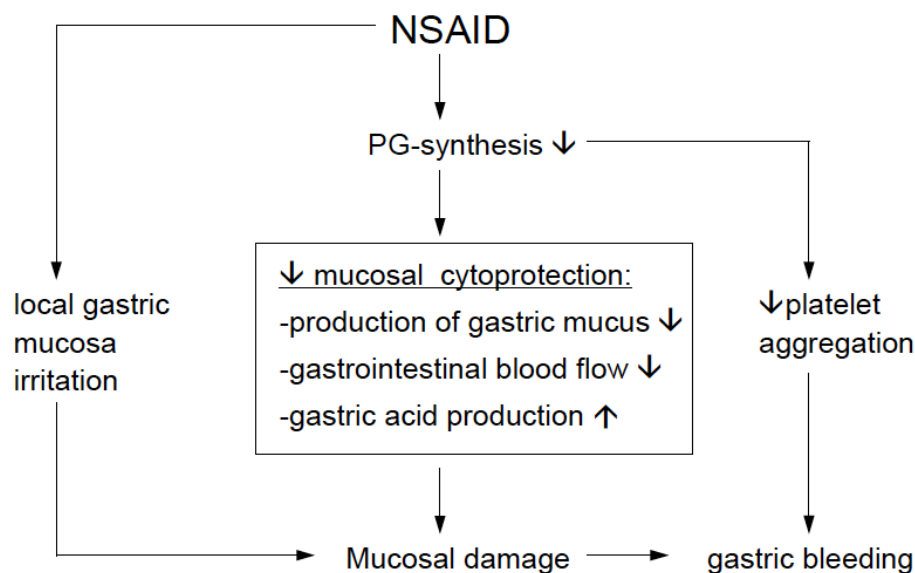

Furthermore, Coxibs may increase the risk of cardiovascular events for long term exposition (see below).

Coxibs do not inhibit platelet aggregation and do not lengthen bleeding time; this, combined with the decreased risk of peptic complications reduces the risk of gastro-intestinal bleeds (Figure 2). Of course, gastro-intestinal risk not only depends on the drug but also on the dose used daily, patient characteristics (e.g. age),

concomitant medication, the disease treated (e.g. osteoarthritis versus rheumatoid arthritis) and disease activity (Figure 3).

Beneficial effects that can be expected of NSAIDs are improvement of patient's global evaluation of disease activity, pain, and morning stiffness; these drugs have no effect on erythrocyte sedimentation rate (ESR) joint swelling or radiological progression (Gotzsche 1990). NSAIDs do not change the course of RA like disease modifying drugs (DMARDs); this means that they are no substitute for DMARDs in active RA, because joint damage will continue, possibly even at a higher rate due to the elevated pain threshold, leading to easier overuse of inflamed joints.

Figure 2: Effects of NSAID locally on gastric mucosa and systematically on gastrointestinal and platelet physiology, leading to gastric complications, especially bleeding.

↓ = decrease; ↑ = increase

2.2-NSAIDs tolerance

Several adverse-effects are clearly related to the specific COX iso-enzyme, in contrast to other adverse-effects, e.g. on the kidney (Gooch et al. 2007), (Table 4).

2.2.1-Digestive toxicity

The inhibition of COX-1 by NSAIDs increases the risk of gastric or duodenal ulcer (Figure 2). Several risk factors have been identified (Figure 3). This potential toxicity is not influenced by the route of administration (oral or parenteral) and is similar whether the drug is taken during the meals or not (the gastric toxicity is not due to the presence of the NSAID in the upper digestive tract but to its action once absorbed and circulating in the serum).

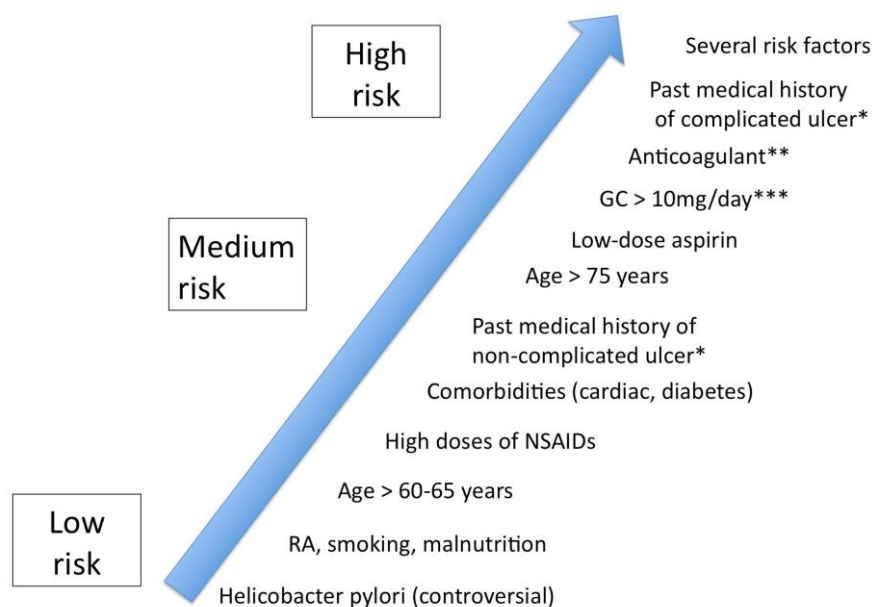

The toxicity of NSAID on gut can also occur in the lower digestive tract (small intestine, colon and rectum), with a higher risk associated with NSAID suppository.

Table 4: Adverse effects of NSAID; between brackets examples of drugs known to cause this adverse effect

Related to inhibition of COX	
◇	Bleeding due to inhibition of platelet aggregation (aspirin)*
◇	Fluid and sodium retention, with clinical manifestations: Hypertension, oedema, congestive cardiac failure
◇	Renal insufficiency
◇	Gastric and duodenal ulcers (piroxicam)
◇	Bronchospasm (aspirin)
◇	Central nervous system dysfunction, headache (indomethacin)
Not related to inhibition of COX	
◇	Rise in transaminases, hepatitis (diclofenac, phenylbutazone, sulindac)
◇	Rash (piroxicam, sulindac, tolfenamic acid)
◇	Pseudoporphyria (naproxen)
◇	Neutropenia, thrombocytopenia, red cell aplasia (phenylbutazone)
◇	Pulmonary infiltrates (naproxen)
◇	Cystitis (tiaprofenic acid)
◇	Interstitial nephritis (fenoprofen)

* Inhibition of platelet aggregation is used as therapeutic effect of aspirin

Figure 3: risk factors for digestive toxicity of NSAIDs

The more risk factors present, the higher the risk is.

* Gastric and/or duodenal ulcer; **anticoagulant or/and antiplatelet therapy; ***GC, glucocorticoids > 10 mg equivalent prednisone per day.

Proton pump inhibitors (PPIs) are able to inhibit gastric acid secretion and are efficacious in healing NSAID-associated ulcers. PPIs also demonstrated efficacy in reducing the risk of ulcerations associated to NSAID use in comparison with NSAIDs alone in randomized controlled trials (RCTs) (Scheiman 2013). The actual risk of NSAID-induced upper gastrointestinal complications could be less however, if patient compliance to the protective medication and physician compliance to therapeutic guidelines was improved (Dincer et al. 2006; van Soest et al. 2007; Vonkeman et al. 2007). Eradication of *Helicobacter pylori* infection does not prevent occurrence or recurrence of NSAID-induced peptic ulcers (Chan et al. 1997; de Leest et al. 2007).

2.2.2-Renal toxicity

All NSAIDs are associated with renal adverse events. NSAIDs can increase sodium retention, increasing the risk of hypertension and exacerbations of congestive heart failure (Table 5). Acute renal failure due to NSAIDs use is uncommon but can be caused by its vasoconstrictive effects and acute interstitial nephritis (Crofford 2013). Based on a cohort study of 4101 RA patients, the use of NSAIDs was an independent factor for accelerated decline of renal function in patients with an estimated glomerular filtration rate (eGFR)<30ml/min but this negative effect not observed in patients with higher eGFR (Moller, Pruijm et al. 2013).

Table 5: Renal side-effects of NSAID*

Side-effect	Mechanism**	Risk factor***
Sodium retention	↓ prostaglandin synthesis: intrinsic effect of NSAID	<ul style="list-style-type: none"> • dehydration, diuretics • heart failure
Hyperkalaemia	↓ prostaglandin synthesis → hyporeninaemic hypoaldosteronism: intrinsic effects of NSAID	<ul style="list-style-type: none"> • renal diseases • heart failure • diabetes mellitus • multiple myeloma • K⁺-sparing diuretics
Acute deterioration of renal function	↓ prostaglandin synthesis: intrinsic effect of NSAID	<ul style="list-style-type: none"> • renal diseases • heart failure • diabetes mellitus • dehydration, diuretics • old age
Nephrotic syndrome with interstitial nephritis	↑ interstitial lymphocyte recruitment and activation: idiosyncrasy / allergy	<ul style="list-style-type: none"> • fenoprofen
Papillary necrosis	cumulative toxicity	<ul style="list-style-type: none"> • Phenacetin • diabetes mellitus? • sickle cell disease?

* In all cases, therapy is stopping of the NSAID therapy; in some cases dosage can be reduced

**Intrinsic effect: related to mode of action; idiosyncrasy: reaction of an individual patient to a specific drug; direct toxicity: related to (cumulative) dose; ↓ = decrease; ↑ = increase

***Heart failure, dehydration, diuretics: increased angiotensin II or adrenergic states.

2.2.3-Cardiovascular toxicity

All NSAIDs have a potential deleterious effect on cardiac function due to their effect of blood pressure (with an intensity which is different depending on molecule). The risk is maximal in patients with a previous history of heart failure and it has been shown that the NSAID use in this population is associated with a risk of congestive heart failure (McGettingan et al, 2006; Bhala et al, 2013; Ungprasert P et al, 2016).

The risk of cardiac ischemic disease such as angina pectoris or myocardial infarction is more complex to establish. Naproxen seems to have a low risk on cardiovascular events (Scheiman 2008). Recent findings from a very large meta-analysis of clinical trials of NSAIDs may now allow physicians to quantify the cardiovascular and gastrointestinal risks associated with these drugs. The results of the Coxib and traditional NSAID Trialists' (CNT) Collaboration, employing data from more than 350,000 randomized patients, show that the risk of major vascular events— mostly major coronary events— was increased by one-third in people taking coxibs or high-dose diclofenac. Ibuprofen significantly increased the risk of major coronary events but not major vascular events. Compared with other traditional NSAIDs (not coxibs), high-dose naproxen was not associated with an increased risk of major vascular or coronary events.

Some authors have hypothesized a class effect of coxibs with regards to the risk of cardiovascular events, notably myocardial infarction. Actually, such a risk has been identified for rofecoxib when used daily for more than 1 year (which has led to the withdrawal of the drug off the market) (Bombardier, et al 2000; Chan et al, 2006; Psaty and Weiss 2007). More recent studies indicate that it was probably a drug effect, not observed with celecoxib, another coxib still on the market (McGettingan et al, 2006).

2.3-Choice of an NSAID

For an individual patient, the choice of an NSAID depends on characteristics of that patient (Table 6). Coxibs or non COX-specific NSAID should be used at the lower end of the recommended dose ranges, since the risk adverse effects increases with the dose (Gotzsche 1989; Psaty and Furberg 2005). If the effect is insufficient, the dose can be increased or the drug can be combined with analgesics to avoid adverse effects (Seideman and Melander 1988; Seideman 1993). The association with glucocorticoids should be avoided, due to increase risk of cardiovascular and gastrointestinal toxicity. In patients with chronic kidney disease chronic NSAID or coxib therapy should be avoided (Gooch et al. 2007). Other advice for prescription is given in table 7.

NSAIDs with long acting effect are particularly useful to control nocturnal awakening and morning stiffness. They can be for instance taken in the evening, before going to sleep, and the sustained release drug formulation will be active during the second part of the night.

Table 7: Advice for prescription of analgesics, NSAIDs and Coxibs for RA

- Pain in active RA is effectively and preferentially treated by DMARD
- Be aware of contra-indications, e.g. allergic asthma, renal insufficiency
- It is sensible to start with acetaminophen and to add a NSAID and Coxib, if needed
- Choice of a specific NSAID
 - ◊ use a frequently used NSAID with known (low frequency of) side-effects
 - ◊ if increased risk of peptic ulceration and low risk of cardiovascular disease: prescribe a COX-2 selective NSAID
 - ◊ if presence or increased risk of cardiovascular disease: avoid NSAID, especially COX-2 selective NSAID
- Prescribe one NSAID at a time; there is no evidence for synergism for 2 or more
- Prescribe the lowest clinically effective dose for a fixed period of time (e.g. 2 weeks), before deciding on therapeutic effect
- In case of insufficient effect:
 - ◊ the dose can be increased, but the increase in effect obtained with the highest doses of NSAID is small and the highest doses cause more adverse-effects
 - ◊ the addition of an analgesic to a medium-dose NSAID results in a better effect and less risk of adverse-effects compared to the highest dose of the NSAID
- Do not use a NSAID or prescribe a COX-2 selective NSAID or add co-medication to the NSAID for gastric protection if there is a history of peptic ulceration or if 2 or more of the risk factors for (complications of) peptic ulceration are present:
 - ◊ concomitant use of anticoagulants
 - ◊ age over 60 years
 - ◊ concomitant use of glucocorticoids
 - ◊ active RA, especially when leading to immobility
- Be aware of drug interactions with NSAID:
 - ◊ *cyclosporin, ACE-inhibitors*: (increase of) renal failure
 - ◊ *diuretics and antihypertensives*: reduced effect due to sodium retention
 - ◊ *cyclosporine*: increased risk of hypertension
 - ◊ *ACE-inhibitors, potassium-sparing diuretics*: risk of hyperkalaemia
 - ◊ *anticonvulsants*: increased effect due to competitive protein binding
 - ◊ *lithium, methotrexate and digoxin*: increased effect of these drugs due to reduced renal clearance induced by NSAID
 - ◊ *methotrexate*: increased risk of liver enzyme elevations (diclofenac)
 - ◊ *aspirin (acetylsalicylic acid)*: decrease of therapeutic platelet aggregation by ibuprofen
 - ◊ *anticoagulants*: increased effect due to inhibition of platelet aggregation
- Check blood pressure, haemoglobin, serum liver enzymes and creatinine regularly

Table 6: Example of a simple scheme for prescription of NSAID, coxibs and gastro protection (PPI, proton pump inhibitor) for patients with RA, according to cardiovascular (CV) and upper gastrointestinal (GI) risk

	GI-risk low	GI-risk moderate	GI-risk high
CV-risk low	Any NSAID	NSAID & PPI or coxib	Coxib & PPI
CV-risk moderate	NSAID, preferentially naproxen	NSAID, preferentially naproxen & PPI	Naproxen & PPI or Coxib & PPI
CV-risk high	Naproxen	Naproxen & PPI	No NSAID nor coxib

3. Glucocorticoids

Glucocorticoids (predniso(lo)ne, dexamethasone) are a unique class of drugs with well-defined effects (table 8 and 9). They are invaluable in the treatment of a range of chronic inflammatory conditions, including RA, because of their rapid and effective mode of action, their pleiotropic well-characterized anti-inflammatory and immunosuppressive effects and long history of use in medicine.

Of the oral glucocorticoids, predniso(lo)ne is most frequently used. Prednisone itself is inactive and hepatically converts to prednisolone, which is the active compound. However, prednisolone is less well absorbed and has a less good bioavailability than prednisone. That is why this latter is often preferred in the treatment of RA.

With normal renal function it is quickly eliminated. It can be used in pregnancy and during lactation at the lowest effective dose, since high doses may lead to fetal immunosuppression or gestational diabetes (Göstetam Skorpen et al. 2016).

Table 8: Main corticosteroids derivatives.

The anti-inflammatory and mineralocorticoid effects of each molecule are estimated in comparison with hydrocortisone, which stands for reference. The inhibitory effect is related to the slowing down effect on the adrenal axis.

Effect	Anti-inflammatory	Mineralocorticoid	Effect duration (hours)
Hydrocortisone*	1	1	8-12
Prednisone	4	0.8	12-24
Prednisolone	4	0.8	12-24
Methylprednisolone	5	0.5	12-24
Triamcinolone (F)	5	0	24-36
Betamethasone (F)	25	0	> 36
Dexamethasone (F)	30	0	> 36

*Cortisol and hydrocortisone the same molecule, cortisol being endogenous, hydrocortisone being the name given to the medication. F = fluor derivative

Table 9: Glucocorticoid equivalence table

Prednisone	5 mg
Hydrocortisone	20 mg
Prednisolone	5 mg
Methylprednisolone	4 mg
Triamcinolone	4 mg
Bethamethasone	0.75 mg
Dexamethasone	0.75 mg

3.1- Glucocorticoids as DMARDs

Glucocorticoids provide actual clinical and radiological benefits in RA: various COCHRANE meta-analyses showed that short-term or moderate-term low-dose corticosteroids were clinically superior to placebo or NSAIDs (Criswell et al. 2000; Gotzsche et al. 2004), but also structurally, as they reduce the rate of radiological progression in RA. Indeed, low-dose glucocorticoids (≤ 10 mg prednisone daily equivalent, or 0.1 mg/kg/day) slow the rate of joint damage and this rate may increase when glucocorticoids are stopped (Kirwan et al, 2007). A meta-analysis even suggested that glucocorticoids would have a structural effect (in absolute value) similar to Disease Modifying Anti-Rheumatic Drugs (DMARDs) and close to biotherapies (Graudal et al. 2010). However, glucocorticoid monotherapy is not specifically recommended by the EULAR Task Force and should only be used in exceptional cases when all other DMARDs have contraindications (Smolen et al., 2014; Smolen et al, 2016).

When combined with csDMARDs, glucocorticoids increase clinical, functional and structural efficacy (Bakker et al., 2012; Svensson et al. 2005; Landewe et al. 2002; Wassenberg et al. 2005), and this combination has similar efficacy when compared with TNF inhibitors plus methotrexate (Heimans et al. 2013; Goekoop-Ruiterman et al. 2005). The beneficial effects on joint damage have been convincingly shown in several clinical trials in patients with early RA (disease duration up to 2 years, possibly up to 4 years), in whom prednisone at a mean daily dose of 6.3 mg (range 0.7–15.9 mg) was added to other DMARDs, resulting in a reduction of about 50% in the rate of progression of radiographic erosion. In studies lasting 2 years, the benefit was slightly lower in the second year but was still significant. Glucocorticoids have therefore been progressively accepted as DMARDs in early RA (Kirwan et al. 1995; Bijlsma et al. 2006) and, by many, as part of the initial treatment plan. These structural effects seem to be maintained even after glucocorticoids are stopped (Mouterde et al, 2010; Bijlsma, 2012).

3.2- Glucocorticoids side effects: less interesting profiles than csDMARDs or bDMARDs

Studies on harm are often of low quality: observational designs with high risk of bias (especially confounding by indication), poor documentation of glucocorticoid exposure and differing models of risk attribution.

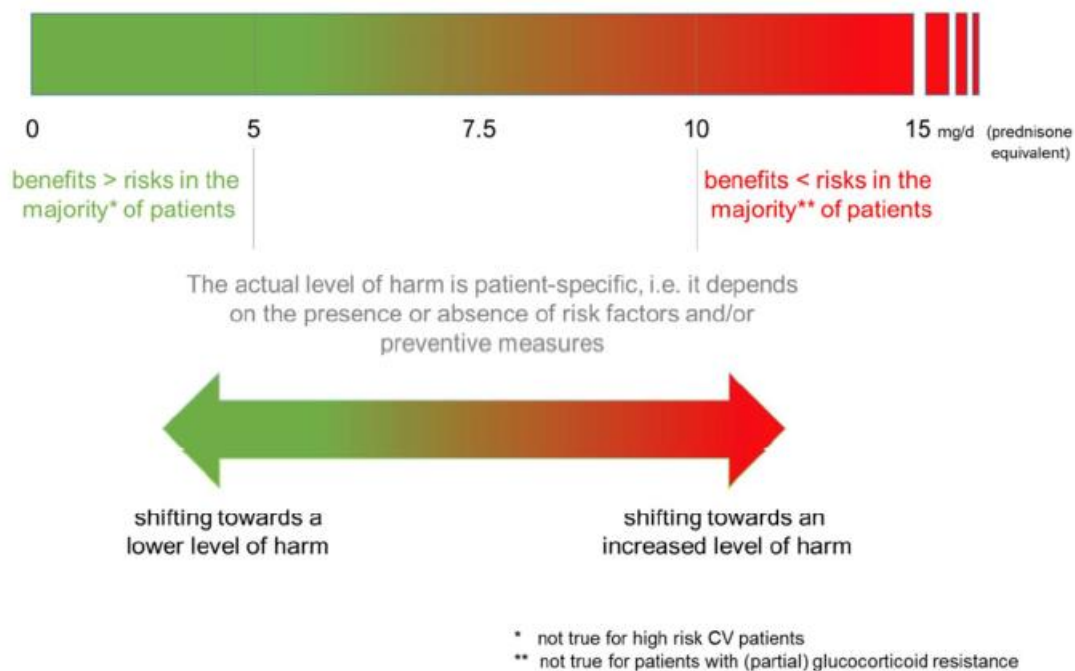

Moreover, clinical trials of glucocorticoids have often been small, short and with limited assessment of adverse events (Strehl et al. 2016). Nevertheless, glucocorticoid treatment, notably with high doses, is associated with serious side effects, such as osteoporosis, hyperglycaemia, hypertension, skin fragility, peptic ulcer disease, premature atherosclerosis, cataracts, myopathy, osteonecrosis, infection (eg, reactivation of latent tuberculosis), mood changes, sleep disturbances and weight gain (Table 10). In addition, the data from the German RABBIT registry clearly showed that steroids are associated with an increased mortality in RA, contrarily to csDMARDs or bDMARD (Listing et al, 2015) (Table 10).

Table 10: Excess mortality risk associated with corticosteroids (adapted from Listing 2015).

	Unadjusted HR		Adjusted HR: 6 (rituximab 12) months risk window approach			Adjusted HR: Ever exposed approach			Deaths	PYRS
	HR	95% CI	HR	95% CI	p Value	HR	95% CI	p Value

Evidence for the risks of low-dose glucocorticoid treatment is scarce, and several controlled randomized clinical trials have shown that the frequency and severity of adverse reactions is often not statistically different from that of placebo. Nevertheless, data from registries suggest that concern remains about potential long-term adverse reactions to glucocorticoid therapy, such as increased cardiovascular risk. Recently, a multidisciplinary EULAR Task Force aimed at defining conditions under which long-term glucocorticoids may have an acceptably low-level of harm (Strehl et al. 2016). The group agreed that the risk of harm is low for the majority of patients at long-terms dosages of ≤ 5 mg prednisone equivalent per day (with the exception of patients at high risk for cardiovascular diseases), whereas at dosages of > 10 mg/day the risk of harm is elevated. At dosages between > 5 and ≤ 10 mg/day, patient-specific characteristics (protective and risk factors) determine the risk of harm (Figure 3). Hence, the level of harm of glucocorticoids depends on both dose and patient-specific parameters, and general and glucocorticoid-associated risk factors and protective factors such as healthy lifestyle should be taken into account when evaluating the actual and future risk (Figure 3, Strehl et al. 2016). Screening and monitoring for adverse events as part of standard care in clinical practice should therefore be performed (van der Goes et al, 2010) (Table 10).

Figure 3. The level of harm of long-term glucocorticoid therapy in rheumatic diseases (Strehl et al, 2016).

Bearing in mind the beneficial effects of glucocorticoids, the Task Force members agreed that at dosages of ≤ 5 mg/day prednisone equivalent, there is an acceptably low level of harm that is elevated at dosages of >10 mg/day. At dosages between >5 and ≤ 10 mg/day, there still exists uncertainty and therefore patient-specific characteristics (ie, disease activity, the presence of additional risk factors) need consideration when estimating the risk of harm. These patient-specific factors can shift the level of harm towards the better or worse.

Table 11: Main adverse effects of glucocorticoids and their management

Side effects	Prescreening, prevention and monitoring
Cardiovascular: <ul style="list-style-type: none"> ➤ Hypertension ➤ Perturbation of serum lipoproteins ➤ Premature atherosclerotic disease ➤ Arrhythmias with pulse infusions 	<ul style="list-style-type: none"> ➤ Blood pressure measure ➤ Weight measures, and lower limb oedema detection ➤ Electrocardiogram, especially before pulse infusions ➤ Serum lipid profile
Endocrine and metabolism: <ul style="list-style-type: none"> ➤ Weight gain ➤ Diabete mellitus ➤ Hypothalamic-pituitary-adrenal insufficiency 	<ul style="list-style-type: none"> ➤ Regular weight measures ➤ Dietician consultation, low sugar and salt diet ➤ Regular fasting glycaemia measures ➤ Patient education: never stop medication without medical agreement
Renal: <ul style="list-style-type: none"> ➤ Hypokalemia ➤ Fluid volume shifts 	<ul style="list-style-type: none"> ➤ Regular ionogram check, and potassium supplementation if needed ➤ Weight measures, and lower limb oedema detection
Gastrointestinal: <ul style="list-style-type: none"> ➤ Gastritis, peptic ulcer disease (PUD) ➤ Visceral perforation, diverticulitis ➤ Steatohepatitis ➤ Pancreatitis 	<ul style="list-style-type: none"> ➤ Respect digestive contraindications: avoid prescribing glucocorticoids if medical history of gastritis, PUD, perforation ➤ If prescription cannot be avoided: find the minimally efficacious dose, add PPI* and avoid other gastrotoxic co-medication (especially NSAIDs)
Bone: <ul style="list-style-type: none"> ➤ Osteoporosis ➤ Avascular necrosis 	<ul style="list-style-type: none"> ➤ Detect, prevent and treat (if necessary) osteoporosis: <ul style="list-style-type: none"> ○ modify if possible other risk factors (smoking) ○ dietician consultation to increase calcium intakes +/- D-vitamin and calcium supplementation (except if sarcoidosis) ○ osteodensitometry ➤ Find the minimal efficacious dose, and especially avoid too frequent pulse infusions (↑ avascular necrosis)
Infectious disease: <ul style="list-style-type: none"> ➤ Heightened risk of bacterial, viral (herpes zoster) and opportunistic infections ➤ Malignant anguillulosis (if the patient comes from or went to endemic zones) 	<ul style="list-style-type: none"> ➤ Detect and treat potential chronic infectious sources (dental, ear-nose-throat...) ➤ Avoid prescription if chronic uncontrolled infection (AIDS, recurrent urinary infection...) ➤ If pulse infusions: hemogram, cytobacteriological urinary analysis +/- chest X-rays ➤ If at risk: tuberculosis test ➤ If patient at risk for anguillulosis: stool sample and prevention with ivermectin prior to glucocorticoid prescription
Muscle: <ul style="list-style-type: none"> ➤ Myopathy 	<ul style="list-style-type: none"> ➤ Avoid chronic use, or found the minimal efficacious dose ➤ Patient education: sportive activity, rehabilitation
Dermatological and soft tissues: <ul style="list-style-type: none"> ➤ Skin thinning and purpura ➤ Cushingoid appearance ➤ Alopecia ➤ Acne, hirsutism, hypertichosis ➤ Striae 	<ul style="list-style-type: none"> ➤ Avoid chronic use, or found the minimal efficacious dose
Eye: <ul style="list-style-type: none"> ➤ Posterior subscapular cataract ➤ Elevated intraocular pressure, glaucoma 	<ul style="list-style-type: none"> ➤ Detect by regular ophthalmologic assessments, especially in patients at risk and in the elderly
Neuropsychiatric: <ul style="list-style-type: none"> ➤ Euphoria, dysphoria/depression ➤ Insomnia/akathisia ➤ Psychosis ➤ Dizziness 	<ul style="list-style-type: none"> ➤ Respect the psychiatric contra-indications: bipolarity, psychosis
Genitourinary and reproductive: <ul style="list-style-type: none"> ➤ Amenorrhea, infertility ➤ Gestational diabetes ➤ Intrauterine growth retardation 	<ul style="list-style-type: none"> ➤ Avoid if possible during pregnancy. If not possible, find the lowest effective dose ➤ Tight maternal and foetal monitoring during pregnancy: intrauterine growth, gestational diabetes detection and prevention...

*PPI: proton pump inhibitor; NSAIDs, Non-Steroidal Anti-Inflammatory Drugs; ↑, increase; AIDS, Acquired Immune Deficient Syndrome; CBC, complete blood count.

3.3- Glucocorticoids as “bridging therapy”

Although the efficacy of GCs is well recognized, and although most studies on their toxicity are of low quality and short duration, the EULAR taskforce felt glucocorticoids toxicity, particularly in the intermediate to long term, should not be disregarded and thus glucocorticoids should be used with caution and preferably for only short periods of time. Thus GCs were proposed for a limited period, as “bridging therapy” while waiting for a DMARD to reach full effect, with the goal of tapering the GC dosage or stopping the GC as soon as allowed by the clinical situation, due to its cumulative toxicity. Hence, the 2013 and 2016 update EULAR recommendations stipulate that “low-dose glucocorticoids should be considered as part of the initial treatment strategy (in combination with one or more csDMARDs) for up to 6 months, but should be tapered as rapidly as clinically feasible” (Smolen et al, 2014; Smolen et al, 2016). Different strategies have been proposed for “bridging therapy” for example, prednisone at moderate doses (10–30 mg/day), at high doses (30–60 mg/day) to induce remission in conjunction with another DMARD (usually MTX), followed by rapid tapering to the lowest effective dose, as used in the COBRA trial, or at low doses (5–10 mg/day), in combination with another DMARD, to maintain a state of low disease activity (Gaujoux-Viala et al. 2014). Some teams prefer 1 to 3 intramuscular injections or intravenous infusions of methylprednisolone, which might have the advantage to limit the risk of chronic use (Gaujoux-Viala et al. 2014). Glucocorticoids should not be considered as a long-term treatment of RA.

When stopping or tapering glucocorticoids after the initial 6 months of “bridging therapy” is not possible, the minimal efficient dose should be the goal, ideally below 0.1 mg/kg/day, which is considered by many as acceptable (Strehl et al. 2016). In case of important polyarticular flairs and/or of visceral impairment (mainly vasculitis), intravenous or intramuscular boluses of methylprednisolone might be used. Detailed recommendations by the EULAR Task Force for the management of medium- to high-dose glucocorticoids have been published (Duru et al, 2013). Another Task Force established recent recommendations for long-term glucocorticoid treatment (Strehl et al. 2016).

3.4- Local intra-articular injections of glucocorticoids

This point will be developed in **In-Depth Discussion 3** (www.eular-onlinecourse.org)

EULAR on-line course on Rheumatic Diseases

Treatment of rheumatoid arthritis

Bruno Fautrel, Stéphane Mitrovic, Peter Taylor

A previous version was co-authored by Peter Taylor, Elsa Vieira-Sousa, João Eurico Fonseca

IN-DEPTH DISCUSSION III

**Local and non-pharmacological therapeutics in the
treatment of rheumatoid arthritis**

Introduction

Rheumatoid arthritis care is not limited to the prescription of Disease-Modifying Antirheumatic Drugs (DMARDs) or symptomatic drugs. It should also include:

- Patient education and counselling performed by the rheumatologist, a rheumatology nurse or physiotherapists (see In-Depth Discussion 1, www.eular-onlinecourse.org) in order to improve patient knowledge and skills to face the disease. It could include learning of self-administered techniques to better cope with pain and anxiety related to the disease.
- Local therapies when needed, mainly intra articular injections in case of active synovitis or surgery (Fontaine 2014) when a joint is severely and irreversibly damaged.
- Non-drug therapies which includes physiotherapy, rehabilitation occupational therapy.
- Diets (Combe et al. 2016).

1. Patient education

Patient education aims to improve patient skills to accept the RA diagnosis and face RA consequences in the activities of daily living. Patient education and counseling (PEC) should be conducted by a multidisciplinary team including the rheumatologist and the other rheumatology health professionals, i.e., rheumatology nurses, physiotherapist, ergotherapist, etc... (Zangi et al, 2015) (see In-Depth Discussion 1, www.eular-onlinecourse.org). The PEC programs need to be structured and 4 main steps have been identified (Table1):

Table 1: main steps and aims of patient education and counselling:

Steps	Aims
- Educational diagnosis:	To identify the patient educational / learning needs To identify the key motivation points that could be used
- Learning objectives	To define the objectives shared by the patient and the health professionals to be addressed during the program
- Hierarchized action plan	To define the number, the order and content of the educational sessions
- Evaluation	To assess the skills, knowledge and competences that the patient should have achieved during the educational sessions To identify the potential remaining educational needs that could be targeted by future sessions.

In addition, the learning and training of specific self-administered techniques such as relaxation, hypnosis, sophrology or mindfulness could facilitate the patient ability to cope with fatigue, pain and anxiety, which are often associated with RA.

Recently, a EULAR Task Force has established overarching principles and recommendations for education for people with inflammatory arthritis (Zangi et al, 2015) (table 2):

Table 2: EULAR recommendations for patient education for people with inflammatory arthritis (Zangi 2015)

<i>Overarching principles</i>		
1. Patient education is a planned interactive learning process designed to support and enable people to manage their life with inflammatory arthritis and optimise their health and well-being		
2. Communication and shared decision making between people with inflammatory arthritis and their healthcare professionals are essential for effective patient education		
Recommendations	Category of evidence	Strength of recommendation
1. Patient education should be provided for people with inflammatory arthritis as an integral part of standard care in order to increase patient involvement in disease management and health promotion	1A-2B	A-C
2. All people with inflammatory arthritis should have access to and be offered patient education throughout the course of their disease including as a minimum; at diagnosis, at pharmacological treatment change and when required by the patient's physical or psychological condition	3-4	C-D
3. The content and delivery of patient education should be individually tailored and needs-based for people with inflammatory arthritis	1B	A
4. Patient education in inflammatory arthritis should include individual and/or group sessions, which can be provided through face-to-face or online interactions, and supplement by phone calls, written or multimedia material	1A-B	A
5. Patient education programmes in inflammatory arthritis should have a theoretical framework and be evidence-based, such as self-management, cognitive behavioural therapy or stress management	1A-B	A
6. The effectiveness of patient education in inflammatory arthritis should be evaluated and outcomes used must reflect the objectives of the patient education programme	4	D
7. Patient education in inflammatory arthritis should be delivered by competent health professionals and/or by trained patients, if appropriate, in a multidisciplinary team	3	C
8. Providers of patient education in inflammatory arthritis should have access to and undertake specific training in order to obtain and maintain knowledge and skills	3-4	C-D

2. Local treatments

Local therapies include intra articular injection, as well as orthopaedic procedures. Intra articular therapies are used in complement of systemic DMARDs when persistent synovial inflammation remains in one or a limited number of joints. Two drug categories can be injected:

- Steroids in the majority of the cases;
- Isotopic compounds less frequently, after the failure of steroid injections.

For small joints or for injections with the most powerful compounds, a fluoroscopic or ultrasound guidance is highly recommended to warrant a strictly intra-articular injection and avoid peri-articular soft tissue damage (risk of irreversible cutaneous and subcutaneous atrophy or tendon rupture if injected inside the tendon, which is strictly forbidden).

2.1 Intra-articular steroid injections

Synovial fluid aspiration, also called arthrocentesis, should be done each time when necessary, for diagnostic purposes (synovial fluid analysis) but also for therapeutic reasons. Glucocorticoids, in contrast to the other DMARDs, are also effective as an intra-articular treatment (Hetland et al. 2012). They have an anti-inflammatory effect on synovitis through induction of synovial atrophy, especially fluoride compounds (Table 1). Several preparations for parenteral use are used in clinical practice (Table 3). Although they share common physical and chemical characteristics, these molecules are not identical, and the physician should know the properties of each preparation, and respect the contraindications (Table 4) in order to reduce the risk of side effects (Table 5). Habit is another parameter that might guide the choice of the compound.

Oral information should be given to the patient, and strict measures of asepsis should be taken according to local guidelines. Some teams associate an anaesthetic such as lidocaine, but this attitude is controversial, as it might decrease the steroid efficacy (Dernis et al. 2010). The triamcinolone preparations are less soluble and therefore longer acting but have a slightly higher risk of local skin atrophy. Hence, triamcinolone hexacetonide should be used strictly intra-articularly (which makes fluoroscopic or ultrasound guidance recommended), while other steroids can be used para-articularly (with caution not to inject inside the tendon because this might induce rupture). In some cases, especially for smaller joints, image guided procedures (through X-rays or echography) might be of help to be sure the needle is inside the joint before injection (Mandl et al. 2012). Most of the authors recommend resting the joint for at least 24 hours after the injection, in order to obtain maximal effect (Dernis et al. 2010). Intra articular steroid injections can be renewed up to 3 injections per joint and per year. The failure of 3 injections make quite unlikely that a fourth one will be efficacious quite.

Table 3: main steroids used locally in rheumatoid arthritis

Generic name	Volume	Prednisone equivalence (mg)	Mean effect duration	Solubility	Crystal
Betamethasone phosphate and acetate (combination)	1 mL	40	9 days	+	+
Betamethasone phosphate and dipropionate (combination)	1 mL	46	45 days	+	+(F)
Cortivazol	1.5 mL	62.5	40 days	-	+
Hydrocortisone acetate Prednisolone acetate	5 mL	125	~ 7 days	+	-
Methylprednisolone acetate	1mL 2 mL	50 100	7 days 7 days	+	+/-
Triamcinolone acetonide	1mL (40mg) 1mL (80mg)	50 100	15-20 days	-	++ (F)
Triamcinolone hexacetonide*	2mL	50	~ 60 days	-	+++ (F)

* Strictly intra-articular use; F, fluorinated

Table 4: Absolute and relative contraindications to intra-articular steroid injections

Absolute	Relative
<ul style="list-style-type: none"> ▪ Active infection: <ul style="list-style-type: none"> ➤ Systemic ➤ Septic arthritis ➤ Local skin infection or dermatosis ▪ Surgical osteosynthesis material or prosthesis ▪ Allergy to an excipient ▪ Osteonecrosis ▪ Severe coagulation disorders* ▪ Severe immunosuppression† 	<ul style="list-style-type: none"> ▪ Diabetes‡ ▪ Hypertension‡ ▪ Patient on haemodialysis¶ ▪ Psychosis or bipolarityϕ ▪ Mild coagulation disorders**

*Especially for deep joints – **especially for deep joints. The procedures depend on local guidelines. A hemostasis specialised advice should be taken if necessary – †The risk/benefit ratio and the degree of immunosuppression should be considered for each patient – ‡Ok if equilibrated, please see table 3 – ¶ Higher risk of infection – ϕRisk of psychiatric decompensation due to the systemic effect. A specialised authorisation should be sought.

Table 5. Main adverse effects of intra-articular steroid injections.

Adverse events	Preventive measures and monitoring
Systemic: <ul style="list-style-type: none"> ➤ ↑ blood pressure ➤ ↑ serum glucose level 	<ul style="list-style-type: none"> ➤ Avoid injection if uncontrolled diabetes and/or blood pressure ➤ Monitor blood pressure and capillary glucose levels, and adapt therapy for the steroid effect period (table 1)
Infection	<ul style="list-style-type: none"> ➤ Follow strict aseptic measures according to local guidelines ➤ Do not proceed to the injection if local skin problem ➤ Do not proceed to the injection if surgical material in the joint
Microcrystalline arthritis	➤ Proceed to synovial fluid aspiration to rule out septic arthritis
Local skin atrophy or periarticular calcifications	<ul style="list-style-type: none"> ➤ Favoured by less soluble steroids and fluorinated preparations ➤ Proceed to a strictly intra-articular injection with triamcinolone hexacetonide, through image-guided injection if necessary
Tendon rupture	➤ Never inject inside a tendon
Allergic reactions	➤ Rare, usually related by excipients and not steroid itself
Minor reactions: vasovagal response, flush	<ul style="list-style-type: none"> ➤ Patient reassurance ➤ Prefer a lying flat position for the injection

2.2 Radioisotopic synoviortheses

Radioisotopic synoviortheses are rarely used nowadays, but they can be of great help, in case of persisting synovitis despite 3 steroid injections. They are contraindicated in women of childbearing age.

They consist in colloids containing radioisotopes, injected directly inside the joint, with the purpose of inducing an atrophy of the synovitis. The choice of the radionuclides depends on their physical properties and the joint to treat (table 6). Yttrium penetrates further, and should be reserved for the knee. Although radionuclides can in theory be used in the youth, because the gonadic irradiation is low, radioisotopic synoviortheses of the hip should be avoided before the age of forty. The treatment is generally well tolerated, but can lead to severe skin necrosis if not strictly intra-articularly injected. Hence, the injection should be image-guided to be sure that the needle is inside the joint, and measures of radioprotection taken to prevent complications (Brillouet et al. 2005). A corticosteroid is often added in order to prevent rare painful reactions, and the joint should be rested for at least 48 to 72 hours.

Table 6. Pharmacological characteristics of radioisotopic medications.

Radionuclide	Physical period (days)	Therapeutic indications in RA	Doses
169 Erbium	9.5	Small joints of the hand or feet	Distal or proximal interphalangeal joint: 10 to 20MBq Metacarpophalangeal joint: 20 to 40 MBq Trapezometacarpal joint: 20 to 80 MBq
186 Rhenium	3.7	<ul style="list-style-type: none"> Shoulder Elbow Wrist Hip Ankle 	Shoulder, elbow, wrist and ankle: 70 MBq Hip: 110 MBq
90 Yttrium	2.7	Knee	112 to 222 MBq per joint

MBq, Megabecquerel.

Synoviorthesis with osmic acid are nowadays very rarely used and even contraindicated in some countries, because less tolerated and more difficult and dangerous to prepare (Brillouet et al. 2005).

2.3 Surgery

2.3.1 - Generalities

The development of new treatments of RA over the two past decades have drastically reduced surgical indications and considerably modified the clinical presentation of the patients. Whatever the surgical procedure, there is a significant trend for a reduction of the need of these procedures in RA patients, which highlights the progressing efficacy of cs and bDMARD (Momohara et al, 2010) (Figure 1).

2.3.2 - Overview of the surgical procedures

The main goals of surgery are: to remove (or at least relief) pain, and to maintain or restore function which doesn't always correspond to restoration of a "close-to-normal" anatomy (*Fontaine 2014). The different surgical techniques are:

- Synovectomy, ideally performed under arthroscopy (shaving and joint lavage), after the failure of steroid injections; tenosynovectomy can also be performed in case of persistent tenosynovitis which exposes the patient to a significant risk of tendon break;
- Tendon rupture repair
- Stabilization surgery to prevent further joint dislocation or tendon break (e.g., Sauve-Kapandji procedure in the wrist) (Figure XYZ) (Figure 2).
- Finally, total joint replacement when cartilage and subchondral bone loss is too important.
- Surgery of nervous complications

Figure 1: Biannual number of surgeries for Japanese outpatients with rheumatoid arthritis (RA) participating in a single institute-based large observational cohort (IORRA) (Momohara et al, 2010). Data on the number of outpatients and operations were collected from April to May and October to November each year from 2001 to 2007. The number of outpatients is limited for valid response. The joints for arthroplasties mainly included wrist, metacarpophalangeal, elbow and metatarsophalangeal joints. The joints for arthrodeses were interphalangeal, trapeziometacarpal, wrist and ankle joints.

Figure 2. Arthrodesis of the left wrist, and distal radioulnar surgery with Sauvé-Kapandji technique of both wrists.

2.3.3 - Cervical spine management

Involvement of the cervical spine is important, because of the possible fatal complications, and often begins during early stages of the disease, especially during the two first years (Bouchaud-Chabot A, Lioté F. 2002; Zikou et al. 2005). Cervical spine involvement occurs in over half of patients with rheumatoid arthritis (RA). The most common abnormality is atlanto-axial dislocation, followed by atlanto-occipital arthritis with cranial settling and by lesions of the lower cervical spine. Cervical spine involvement usually occurs in patients with severe RA (Bouchaud-Chabot A and Lioté F. 2002). Pain and neurological evidence of spinal cord injury are the main symptoms. The presence of symptoms is not correlated with the severity of radiological abnormalities. Computed tomography and magnetic resonance imaging provide detailed images of the bone and spinal cord lesions. Because the course is unpredictable, conservatively treated patients usually require regular follow-up (Bouchaud-Chabot A and Lioté F. 2002).

Surgical indications are nowadays rare. Surgery is in order in patients with pain unresponsive to major narcotics or with progressive neurological impairment (Table 7 and 8) (Bouchaud-Chabot A and Lioté F. 2002). The choice between the anterior and the posterior route depends on the experience of the surgical team. It is reasonable to stabilize the spine before the development of cranial settling or major neurological loss (Ranawat's stage III). The good functional results of spinal surgery are frequently overshadowed by major impairments related to severe peripheral joint disease. Safety is acceptable when somatosensory evoked responses are monitored intraoperatively. Surgery can provide substantial improvements in symptoms, particularly pain.

Table 7. Ranawat's scale from pain (adapted from Bouchaud-Chabot A and Lioté F. 2002)

Stage 0	No pain
Stage I	Intermittent pain responsive to standard analgesics
Stage II	Intermittent pain partially responsive to standard analgesics – need for immobilization by a cervical collar
Stage III	Incapacitating continuous pain unresponsive to analgesics

Table 8. Ranawat's scale for neurological involvement (adapted from Bouchaud-Chabot A and Lioté F. 2002)

Class I	No neurological abnormalities
Class II	Subjective impression of muscle weakness with brisk deep tendon reflexes and dysesthesia
Class IIIA	Moderate objective motor loss leaving some degree of self-sufficiency and/or posterior cord syndrome
Class IIIB	Severe neurological impairment with complete loss of self-sufficiency

2.3.4 - Planification of an orthopaedic surgery

Patients with RA are considered “more fragile” for several reasons: psychological difficulties, higher risk of infection (due to RA per se, but also to treatments, in particular biological DMARDs), more fragile skin (mainly owing to steroids) with a higher risk of post-operative necrosis and complications, more fragile bones (osteoporosis and endosteal resorption) (*Fontaine 2014). Local guidelines for the peri-operative management of pharmacological treatment can be found in each country (see Module 4, www.eular-onlinecourse.org). The majority of them recommend maintaining methotrexate in case of scheduled surgery, because the risk of infection is low. The interruption of other DMARDs, especially biologics, depends on their half-life (Table 9).

Table 9: Half-lives and required interruption of the drug treatments before surgery.

Peri-operative septic risk			Low	Medium	High	Very high
<i>Half-life</i>			<i>2 half-lives</i>	<i>3 half-lives</i>	<i>4 half-lives</i>	<i>5 half-lives</i>
csDMARD						
	Methotrexate	10 hours	Can be continue without discontinuation around surgery			
	Leflunomide	15-18 days*				
	Salazopyrine	6-10 hours				
	Antimalarial	40 days				
bDMARDs						
TNFi	Etanercept	70 hours	10 d ~ 2 w	15 d ~ 2 w	20 d ~ 3 w	25 d ~ 4 w
	Infliximab	~10 days	20 d ~ 3 w	30 d ~ 4 w	40 d ~ 6 w	50 d ~ 8 w
	Adalimumab	~15 days	30 d ~ 4 w	45 d ~ 6 w	60 d ~ 8 w	75 d ~ 10 w
	Certolizumab	10-15 days	30 d ~ 4 w	45 d ~ 6 w	60 d ~ 8 w	75 d ~ 10 w
	Golimumab	10-15 days	30 d ~ 4 w	45 d ~ 6 w	60 d ~ 8 w	75 d ~ 10 w
Anti-IL6R	Tocilizumab	12-15 days	~ 30 days	~ 45 days	~ 60 days	~ 75 days
CTLA4-Ig	Abatacept	15 days	~ 30 days	~ 45 days	~ 60 days	~ 75 days
Anti-CD20	Rituximab	20-22 days	~ 40 days	~ 60 days	~ 80 days	~ 100 days

csDMARDs, conventional synthetic Disease Modifying Antirheumatic Drug; bDMARD, biological DMARDs; TNFi, TNF inhibitors; anti-IL6R, anti-Interleukine 6 receptor; CTLA4-Ig, recombinant fully human protein CTLA-Immunoglobulin; anti-CD20, monoclonal chimeric antibody against Cluster Differentiation 20 (B lymphocytes); d, days; w, week.

*Leflunomide has long persistence because of entero-hepatic circulation. Hence, its interruption is not adequate, but some author proceed to a wash out with cholestyramine in case of high septic risk surgery.

The physician should aim at the lowest glucocorticoids dosage, as they can slow down skin cicatrisation. The therapeutic decisions should ideally be taken in multidisciplinary staffs, between the surgeon, the rheumatologist, the radiologist and if possible the rehabilitation specialist.

3. Rehabilitation and other non-drug therapies

Although rehabilitation's place in the therapeutic strategy has considerably changed over the past 15 years because of the development of very efficacious drug therapies, it is still integral part of the therapeutic arsenal. It is very useful and indicated at all stages of the disease (Combe et al. 2016). There is no real contraindication, although intensity should be modulated according to the evolution of the disease. The objectives are to prevent or limit the deformations, to maintain and improve muscular trophicity, joint mobility and to prevent ankylosis (Combe et al. 2016), with the ultimate goals to improve the personal and social quality of life, to cope with pain disability and to allow maintenance of work ability. Rehabilitation should be lead by a multidisciplinary team of different health professionals: the physiotherapist, the occupational therapist, the podiatrist, and the rheumatology nurse specialist/practitioner (see In-Depth Discussion 1, www.eular-onlinecourse.org).

3.1 Orthoses and splints

Orthoses and splints, although less used nowadays, can play a very important role for pain relief and prevention of joint deformation (Combe et al. 2016) (Figure 3).

Different devices can be prescribed:

- standard devices, often semi-rigid, made of highly resistant fabric;
- or rigid tailor-made devices, made of heat-formable material in order to be perfectly adapted to joints (whatever their deformities) and comfortable to wear for the patients.

Some of these devices are to be worn when the person is inactive (rest orthosis) to facilitate joint rest and tendon/muscle relaxation during RA flare, notably at night. Others are made to be worn during physical activities (function orthosis) in order to make the joint stable during these activities and limit pain and risk of further dislocation. The sooner they are made, the better it is, in order to prevent deformations.

Figure 3. Rest orthosis of the wrist and hand.

3.2 Plantar orthoses

Foot problems are common in patients with RA and the role of the podiatrist is to reduce pain, maintain/improve function and mobility, and to protect the skin and soft-tissues of the foot (see In-Depth Discussion 1, www.eular-onlinecourse.org). Three options are possible:

- Adequate footwear: shoes should be large enough around the MTP joints and flexible enough to take into account toe deformities. In case of joint instability or subluxation, the insole should be more rigid to reduce the mechanical demand on the damaged joint(s).
- Specific custom insole, made in heat-formable material, could be prescribed to homogenize and improve the ground support of the feet. In addition, they could reduce the pressure and mechanical demand on the most damaged foot joints.
- Finally, tailor-made orthopaedic shoes can constitute the only option when the feet are severely damaged and dislocated due to RA.

The podiatrist will provide specialist wound care management for patients with foot ulceration

3.3 Physiotherapy

The physiotherapy should be undertaken as soon as possible in order to prevent deformity or ankylosis, which are difficult to correct once established (Combe et al. 2007). It should be global and adapted to each patient (“personalised”), and the patient should be clearly involved (Zangi et al. 2015). It should be undertaken by specialised physiotherapists and occupational therapists who will teach the patient daily exercises, and *participate to patient education*.

3.3.1 - Physical treatment

Physical treatment such as fangotherapy, cryotherapy, paraffin therapy or balneotherapy can be of help to relieve pain and symptoms, although the level of proof of the efficacy on the disease course is insufficient (Verhagen et al. 2015). In addition, massages of painful anatomic regions could enable the reduction of muscle and tendon contractures and careful passive mobilization of the joints could improve their range of motion.

3.3.2 – Self-exercise learning and training

Physiotherapists actively participate to patient education and can teach them specific self-exercise to:

- reduce stiffness in the morning (Figure 4),
- improve range of motion of the joints,

- strengthen muscles by isometric exercises (muscle contractions with no movement of the joints or limbs) in order to maximize joint stability.

3.4 Occupational therapy

Occupational therapy could be part of rehabilitation or a complementary offer on top of physiotherapy and rehabilitation. Its aim is to help patients performing their usual physical activity, either domestic, leisure or professional.

Occupational therapists have to take into account the nature of patient usual activities of daily living. On this basis, they propose to RA patients specific exercises and training to improve their skills to use their body and joints – especially hands – optimally with regards to their damaged joints, and thus to facilitate their social participation either at home or on the workplace.

Finally, occupational therapists can propose multiple technical aids, among which:

- orthoses (see above);
- specific hand grips for kitchen utensils, kitchenware, pens or keys;
- adaption of the home for doorknob, tap or access to the bath tub;
- adaptation of the work place such as chair and desk adaptations, or more ergonomic keyboard;
- walking sticks, rarely walkers or wheel chair.

Figure 4. Daily exercises against morning stiffness. (Courtesy C Larnicol, A Lambert and P Louvrier)

A. Shoulders. Elbow to the body and bent at 90°, move your forearms to the outside during inspiration. Hands joined, elbows in extension, elevate your arms.

B. Elbows. Hands joined, arms parallel to the body: bring your hands to your breast by bending your elbows. Hands joined on the thigh, arms and forearms in extension: lift your arms while putting your elbows in extension as far as possible.

C. Hands and wrists. Hands joined, fingers not crossed: move your fingers from right to left. Same position: separate your fingers then retighten them.

D. Hands and wrists. With the help of the other hand, gently roll up your fingers, and then your wrists. Do little circles with the too thumbs. When the hands and fingers are too tender or stiffened, these exercises can be done under warm water.

E. Hips and knees. Lying down, feet slightly apart, do “wipers” movements with your feet. Bring a knee to the chest with the help of your two hands. Extend your knee as far as you can while bringing the tip of the foot in your direction.

F. Feet. Do little circles with the top of your feet. Bend and extend your ankles and your toes.

4. Diet

Diet in the treatment of RA is a controversial but important issue that implies at first several remarks:

- studies have so far failed to give clear evidence that a particular diet (or dietary supplements) could have a direct effect on disease activity and symptoms (pain, joint swelling, natural history), although several pathophysiologic hypothesis have been advanced;
- cardiovascular risk is increased in RA (in link with increased risk of diabetes, hypertension and hypercholesterolemia), and muscular loss and osteoporosis are frequent in RA, owing to several factors (inflammation and increased catabolism, glucocorticoids). An adapted alimentation, especially in case of chronic glucocorticoids intake, could help to prevent or/and restore muscular and bone trophicity and decrease cardiovascular risk. The appropriate assessment and advice of a dietetician might be of help (see In-Depth Discussion 1, www.eular-onlinecourse.org);
- although no direct link between RA and obesity exist (on the contrary, increased catabolism induces rather weight loss), RA can occur in obese patients. In this case, heavy weight can worsen weightbearing joint destruction, and once again the help of a dietician is important.

4.1 Can a particular diet directly influence disease activity (pain, joint swelling, natural history) in RA?

Many theories (sometimes seducing) have been generated, but clear scientific evidence is lacking to support them.

4.1.1- Fasting

Several authors have suggested that fasting could decrease inflammation, and thus improve osteoarticular symptoms (Kjeldsen-Kragh et al, 1991). However, no significant benefit on the long term has been demonstrated, and fasting on a long period can be very dangerous and induce nutritional deficiencies.

4.1.2-The exclusion of one or several nutrients

Besides fasting, several authors have suggested that the exclusion of one or several nutrients mainly dairy products, gluten and/or red meats, could also improve disease activity and symptoms (Seignalet, 1992). These hypotheses are based on individual observations in some patients who describe an improvement on symptomatology when suppressing the identified nutrient, and a degradation of pain and symptoms when it is reintroduced. However, studies trying to evaluate the effect of different diets in cohorts of patients with RA did not show consistent results, and their interpretation is not easy (Hagen et al, 2009). Mediterranean diet seems however to have the more reproducible results on disease activity (Smedslund et al, 2010), with a now clearly establish benefit on cardiovascular complications - especially myocardial infarction- (Serra-Majem et al, 2006), which are precisely the first cause of mortality in RA.

4.1.3 - The supplementation in polyunsaturated fatty acid

Supplementation in omega-3 and -6 polyunsaturated fatty acid (through dietary complements often extracted from fish oil) has been proposed, because these unsaturated fatty acids have an anti-inflammatory effect. However, results from randomised controlled are disappointing, because they often require high doses for a too-moderate clinical effect (Goldberg, 2007). Nevertheless, they seem to be harmless, and they can be prescribed to patients who are willing, although their price is sometimes high.

4.1.4 – Other supplementation

Probiotics have been proposed, as there seem to be a dysregulation of gut microbiota in RA (like in other rheumatic disease), but to our knowledge only preliminary results exist in animal models (Abhari et al, 2016), and no concluant randomised controlled trials has been led. It has been suggested that Vitamine D could have immunomodulatory effects in autoimmune diseases (Ishikawa et al, 2016), but the impact of its supplementation on RA activity has not been proven. However, it is essential to optimise vitamine D serum levels, to prevent secondary osteoporosis. Oligo-elements supplementation (zinc, copper, vitamine C, selenium...) has not shown efficacy on disease activity in randomised controlled trials.

Diet and Rheumatoid arthritis, summary points:

- ➔ Patients should have a balanced diet
- ➔ Patients should not fast.
- ➔ Clear scientific evidence is lacking for the recommendation of the exclusion of specific nutrients, such as gluten (except concomitant medically confirmed Coeliac Disease), dairy products or red meats.
- ➔ Mediterranean diet has not proven its efficiency in the control of RA activity; however, it has shown clear benefit in prevention of the cardiovascular risks, which is the main cause of mortality in RA.
- ➔ Scientific evidence is lacking for the systematic prescription of polyunsaturated fatty acids; however, they do not seem to have side-effects, and can be safely prescribed if the patient is willing, having in mind their high price.
- ➔ No “immunomodulatory” (probiotics, vitamin D, oligo-elements) molecule has been identified so far; however vitamin D deficiency can have an impact on secondary osteoporosis, and should be hence corrected.

4.2 The role of the dietitian in the management of RA

The dietitian is an essential health professional for the management of RA, especially required in several situations:

- when glucocorticoids are prescribed, especially if medium to high doses, in order to prevent metabolic complications (hypertension, diabetes, hypercholesterolemia, osteoporosis, etc see In-Depth Discussion 2, www.eular-onlinecourse.org). The dietitian will play an important role in patient education, and prescribe an adapted diet low in quick-release carbohydrates, fat and salt;
- for the prevention and treatment of secondary osteoporosis, through the calcium intakes evaluation, and eventually advice and supplementation;
- in very active and catabolic flares. The dietitian will optimise the patient renutrition, through nutritional complements if needed.

module

EULAR on-line course on Rheumatic Diseases

Immunology and the rheumatic diseases

Rogier Thurlings, Mathijs Broeren, René Toes

A previous version was coauthored by Andrew Cope, Margaret Ma, Xavier Mariette, Elisabeth Zirkzee, Jean Sibilia, Peter J. Charles, Ala Skapenko, Hendrik Schulze-Koops

LEARNING OUTCOMES

- To describe and explain a basic understanding of immunology that is of direct relevance to the pathogenic pathways that underpin autoimmune rheumatic disease
- To describe and explain the cellular and molecular components of the innate and adaptive immune systems, with emphasis on the role and functions of antigen-presenting cells, and cellular and humoral immunity
- To describe and explain how these systems interact to provide robust host defence mechanisms
- To list and characterise the cell subsets and inflammatory mediators contributing to immunity
- To evaluate how aberrations of immunity may predispose to chronic inflammatory immune-mediated pathology

1 Introduction

Rheumatologists commit much of their working life to the care of patients with immune mediated chronic inflammatory disease. Immune and inflammatory reactions underpin these diseases, and so it has become a priority to understand the molecular and cellular basis of the immune response in anticipation that, in the longer term, it will facilitate more accurate diagnosis and inform therapeutic decision making for this complex and heterogeneous group of patients. This module is designed to provide simple and basic knowledge of immunology of relevance to the pathogenic pathways that underpin autoimmune rheumatic disease. We have purposefully not provided a detailed description of the pathogenesis of each immune mediated inflammatory disease, since this will be discussed in depth in subsequent modules.

The inflammatory reaction brings into play both non-specific and highly specific immune mechanisms that couple innate and adaptive immune systems at an anatomical and functional level.

2 What does the immune system do?

Our immune system has evolved to protect us against attack from the universe of foreign pathogens that make up our environment. All living organisms, from the most basic plant to mankind, possess intricate self-defence systems (figure 1). Over the course of evolution, the immune system has become highly sophisticated. For example, the flies in your garden have acquired the oldest immune system (the innate immune system), while species of fish have evolved with an additional, more sophisticated system (the adaptive immune system). Depending on the species, each system has diversified to permit the organism to adapt to its environment.

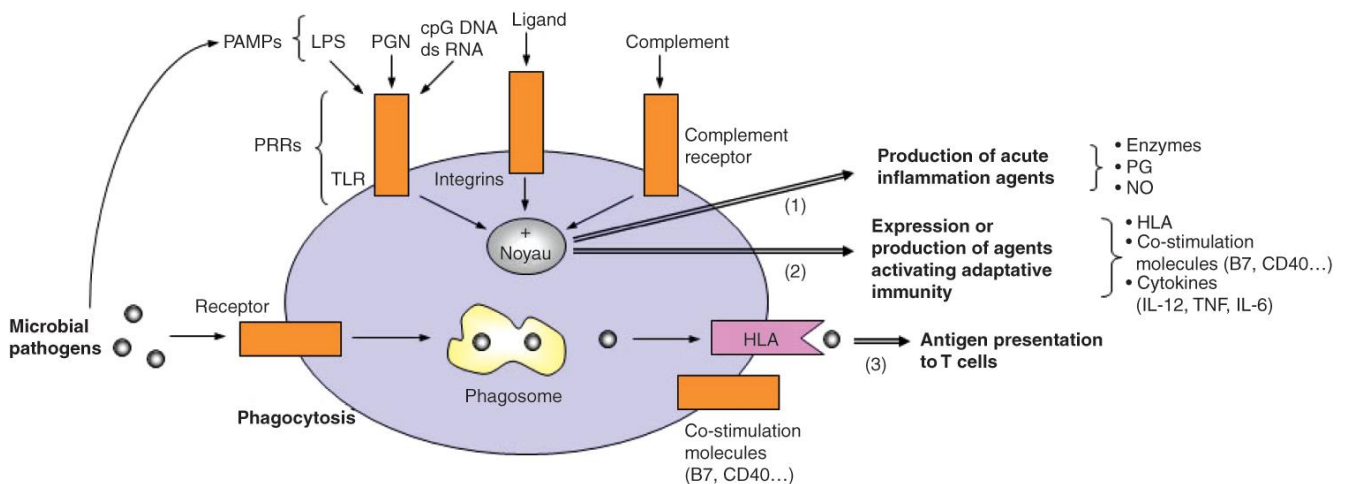

Figure 1 *Phylogeny of the immune response.*

Broadly speaking, every human has two interdependent defence systems: the innate immune system, and the adaptive immune system.

The innate immune system is a succession of immediate responses, which can eliminate external attackers rapidly. This immediate response relies on the instantaneous digestion (phagocytosis) of the 'invaders'. The innate immune system is activated when it recognises molecular patterns that are expressed by prokaryotic organisms (eg, bacteria); these patterns are not expressed by eukaryotic cells like host tissue. Such structures, such as lipopolysaccharide (LPS) or double-stranded RNA, which are only present in bacteria and retroviruses respectively, are recognised by receptors already present in flies. The innate immune system can be activated through the recognition of a variety of such highly preserved microbial constituents that are abundant and shared by numerous species of 'primitive' (prokaryotic) organisms (figure 2). This is a relatively simple and elegant way for the immune system to discriminate between self and non-self, and represents a means by which the immune system can respond rapidly and strongly to invading microorganisms. Although encounter with microorganisms can prime the activation of innate immune cells during follow-up encounters this priming of innate immune system is relatively limited and non-specific and will not result in a response to a second encounter by the same microbe in a more specific way.

Figure 2 A macrophage; as an illustration of how innate immunity senses pathogen associated molecular patterns. CpG, sequence of Cytosine and Guanine in a DNA strand; ds RNA, double stranded RNA; HLA, human leucocyte antigen; IL, interleukin; LPS, lipopolysaccharide; NO, nitric oxide; PAMPs, "pathogen-associated molecular patterns"; PG, prostaglandin; PGN, peptidoglycan; PPRs, "pattern recognition receptors"; TLR, Toll-like receptor; TNF, tumour necrosis factor.

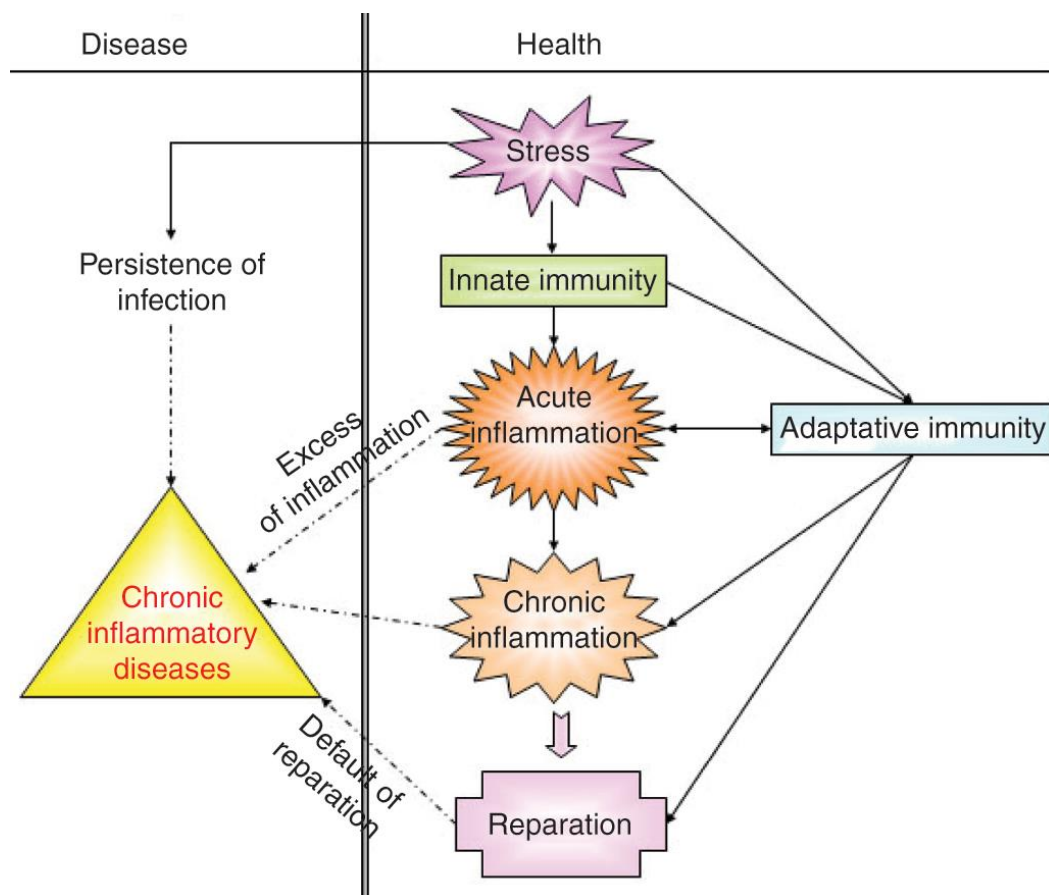

Therefore, next to the innate immune system, another 'immune arm' is present, the adaptive immune response. The adaptive immune response is relatively slow in responding to an invader when first encountered. The cause for this slow reaction is found in the fact that specific cells belonging to the adaptive immune system, the T and B cells, first need to become activated in draining lymph nodes. Here, these cells first divide before they can exert their effector functions. In contrast to the innate immune system, the cells belonging to the adaptive immune system can recognise pathogens in a highly specific fashion. Another

important difference between innate and adaptive immunity is the ability of the adaptive immune response to form a much stronger immunological memory, that allows the highly specific adaptive immune cells to respond as rapid as innate immune cells during a repeat infection. Memory T and B cells are the basis for the success of vaccination against deadly infectious diseases such as smallpox, as they can respond in a highly specific and rapid fashion upon encountering the pathogen, once they have been activated upon vaccination. In doing so, they can eradicate the invading pathogen before it can exert its devastating effects.

Analogous to many living systems, the immune system must function to achieve an equilibrium that will favour host defence against foreign pathogens, while protecting host tissues from collateral damage. To this end, immunity has both strengths and weaknesses. Therefore, a loss in this delicate equilibrium may induce modifications that are likely to become pathological. As an example, an immune deficiency, while seemingly subtle, may promote the emergence of serious infection (often due to a particular species of organism) or, occasionally, neoplastic disease. Conversely, a sustained and unbridled immune response, or a 'badly adapted' immune reaction, may trigger allergic inflammatory and autoimmune disease. The yin and yang of the immune system are the two facets of a complex system that must remain in equilibrium (figure 3).

Figure 3 Sensing environmental cues in health and disease.

3 Molecular and cellular basis of the immune system

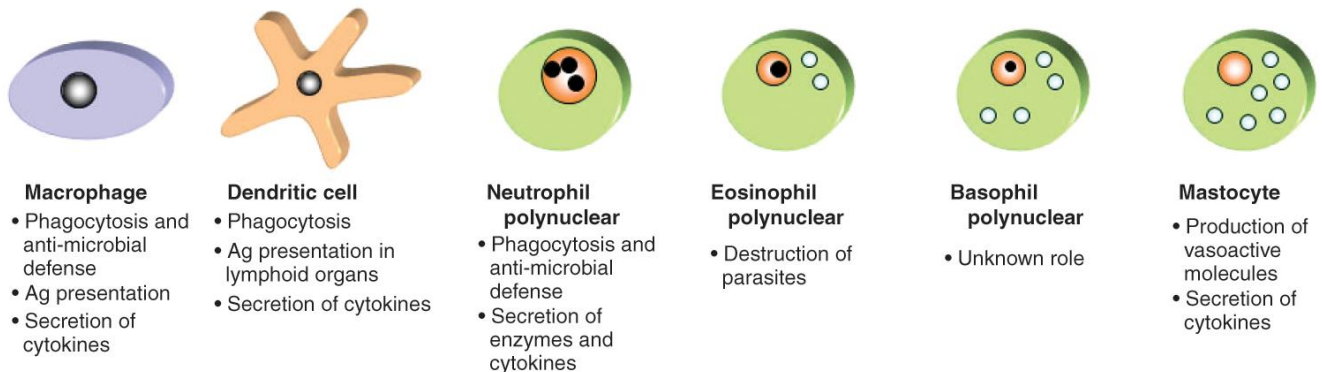

3.1 The cellular players in immunity

Before demonstrating how the score is 'set to music', it is appropriate to first mention the partners required for this 'immune symphony'.

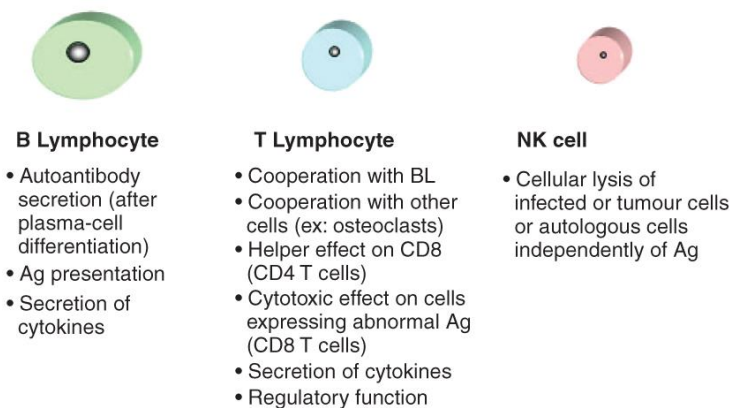

The 'conductor(s)' are those who set the musical score by adding a personal note to this system. These are the central lymphoid organs (thymus, bone marrow), where the immune cells (T and B cells) undertake basic training, and secondary central lymphoid organs (spleen, lymph node, mucous membranes), where 'remedial courses' are conducted. The 'musicians' are the innate immune cells (polymorphonuclear leucocytes, monocyte/macrophages, dendritic cells, mast cells, and natural killer (NK) cells) and those of the adaptive immune system (T and B cells) (figure 4). Only cells of the adaptive immune system require training, whereas innate immune cells have pre-programmed functions. Cells of the immune system are differentiated from each other by different surface molecules. The molecules used for this purpose are described in a protocol termed 'cluster of differentiation' (CD). Every immune cell has specific CD molecules—for example, a cytotoxic T cell is CD3+ CD8+ CD45+.

Figure 4 The cellular basis of immunity. Ag, antigen; NK cell, natural killer cell.

A. Myeloid-derived cells

B. Lymphoid-derived cells

The ‘instruments’ could be viewed as substances synthesised in a highly coordinated manner that enable communication between cells. Communication is received through high affinity receptors that are capable of interacting with specific ligands, such as soluble molecules (cytokines and chemokines) that exercise different functions.

This symphony is performed in a grand concert hall—the human body—which consists of main pathways (circulatory and lymphatic systems), ‘special dressing rooms’ (lymphatic organs), ‘sanctuary’ areas (eg, the eye, testicle), and ‘dedicated organs’ that are specific (eg, skin, joints and kidney).

Next, it is appropriate to discuss in a little more detail, some of the partners required for this ‘immune symphony’.

3.2 The immune cells have one common cellular ancestor

The bone marrow is the ‘progenitor generating centre’ of the immune system since most immune cells originate there before migrating to the peripheral blood, lymphoid organs and thymus.

In the bone marrow, pluripotent precursor cells give rise to:

- myeloid progenitor cells that give rise to the majority of innate immune cells, including polymorphonuclear cells (various types of granulocytes), cells of monocyte/macrophage lineage and dendritic cells, and
- lymphoid progenitor cells that give rise to T and B cells and a specific cell population called NK (natural killer) cells (figure 5A).

3.3 Education of the immune cells in the central lymphoid organs

The maturation of T and B cells occurs, respectively, in the thymus and bone marrow, hence their description as T cells (thymus) and B cells (bone marrow; originally the ‘B’ was derived from the bursa of Fabricius, an organ described in chickens). This maturation consists of stages described as a process of selection of lymphocytes intended to preserve only those cells likely to respond robustly to environmental ‘aggressors’ without attacking the components of the host organism. This latter point is fundamental. In fact, this phenomenon of ignorance or non-responsiveness to self, termed immunological tolerance, is indispensable for avoiding ‘auto-aggression’, which is thought to be the process that underpins autoimmune diseases. The suppression of ‘undesirable’ lymphocytes occurs by a number of processes, including the induction of programmed cell death (apoptosis). Mature lymphocytes, after having received their education in bone marrow and thymus, then leave the central lymphoid organs via the bloodstream in search of their antigen in the peripheral lymphatic organs.

However, as not all antigens recognised by T cells and B cells are expressed in the thymus and bone marrow, respectively, a second system is in place that prevents the induction of potentially harmful responses against self-antigens. Here, dendritic cells play an important role. Dendritic cells are cells with an exquisite capacity to take up antigens in organs and tissues for presentation to T cells in draining lymph nodes. Under normal, homeostatic conditions, the dendritic cells will stay immature and will present antigens under non-inflammatory conditions. Under these conditions, dendritic cells instruct the T cell not to react to the antigens they present either by forcing the T cells to die, or by instructing them to become regulatory T cells—T cells with immune-suppressive functions. The ability of immature dendritic cells to educate the T cells to be tolerant towards antigens of the host (auto-antigens) is vital to the host as many antigens we encounter should not elicit inflammatory reactions. For example, antigens expressed during pregnancy (from the child) or present in the food we eat are in this way prevented from an undesired immune attack.

4 The immune system in action

One way to understand the function of the immune system is to analyse how the most fundamental of responses—defence against pathogens—comes about.

4.1 What happens when a pathogen gains access to the body?

In a patient that is infected by a pathogen, the first line of defence is formed by the innate immune system (figure 5). Firstly, it involves a mechanical defence represented by epithelial barriers, such as skin and mucous membranes. When microbes encroach this barrier, they can induce an inflammatory reaction characterised by a wide range of different inflammatory mediators and selective cell types.

For tissues 'under attack', activation of stromal cells such as epithelium and fibroblasts and resident immune cells (macrophages) is the first step. These cells are activated through recognition of microbe associated molecules known as pathogen-associated molecular patterns (PAMPs), by specific receptors termed pattern recognition receptors (PRRs) (figure 6). These PRRs include well characterised sensors such as those of the Toll-like receptor (TLR) family and NOD-like receptors. Activation of stromal cells and resident macrophages leads to the release of numerous substances, which serve to induce vasodilatation, an increase in the capillary permeability, an influx of additional phagocytic blood cells (dendritic cells, monocytes and polymorphonuclear cells), as well as the generation of inflammatory mediators (box 1).

Figure 5 Initiation of the innate immune response. Ag, antigen; CRP, C reactive protein; DC, dendritic cell; NO, nitric oxide; NPN, normal polymorphonuclear neutrophils; PG, prostaglandins; TL, T lymphocytes.

Different parts in acute phase of inflammation:

1) Microbes activate tissue macrophages by different mechanisms (figure 2). These macrophages secrete different substances vasoactive and pro-inflammatory (cytokines) and other substances (chemokines) attracting other phagocytosis cells (NPN ...)

2) Vasodilatation and increase of vascular permeability allow transfer in infected tissues of proteins (complement, kininogen ...) and of cells specialised in phagocytosis (DC, monocyte, PNN ...)

3) This phagocytosis allows destruction of microbes but also capture of antigens by DC, and macrophages which are reaching lymph nodes by efferent vessels. In these lymph nodes, these Ag-presenting cells (APC) educate and stimulate specific TL.

Figure 6 The different Toll-like receptors (TLRs) and their ligands. LPS, lipopolysaccharide.

These resident and infiltrating innate immune cells and their released substances exert potent antimicrobial effects. Microbes are killed by a variety of mediators, such as proteases (protein cleaving enzymes), lysozyme (an enzyme disrupting the bacterial cell wall) and lactoferrin (a protein that disrupts bacterial metabolism by sequestering iron), in a process assisted by reactive oxygen species (box 1). These mediators can become active after bacteria are taken up inside cells in a process called phagocytosis. They can also be active against microbes as part of DNA networks extruded by innate immune cells in a process called 'extracellular trap formation'. Other mediators, such as natural antibacterial peptides, alarmins and complement, all enhance bacterial killing, activate the surrounding stroma and attract infiltrating immune cells (figure 7). Mast cells, present in tissues together with their products, can also make significant contributions to increasing vascular permeability during the immediate/early phase of the inflammatory response. NK cells kill cells infected by virus.

Box 1 Inflammatory mediators

All these mediators are secreted to defend the organism by eliminating pathogens. However, when they are produced in excessive quantities or when they are hardly eliminated, they may become toxic to the organism.

- **Reactive oxygen species.** These are free radicals derived from oxygen such as superoxide anions (O_2^-) and hydrogen peroxide. In phagocytes, reactive oxygen species are produced in large quantities by the enzyme NADPH oxidase for use in oxygen-dependent killing mechanisms of invading pathogens.

- **Nitric oxide (NO)**

A constitutive NO synthase regulates certain physiological cellular phenomena by production of nitric oxide (NO). If an attack occurs, additional large NO quantities are synthesised due to an induced NO synthase (iNOS). Nitric oxide will then increase vasodilatation and capillary permeability and exert significant toxic cellular effects. The main purpose of this is to eliminate exogenous pathogenic agents.

- **Cell enzymes**

Activated polynuclear cells as well as other cells (synoviocytes, chondrocytes, etc) release numerous enzymes (collagenase, elastase, phosphatase, hydrolase, cathepsine, myeloperoxidase), which play a physiological role in tissue remodelling and homeostasis as well as antibacterial defence.

- **Natural antibacterial peptides (defensins)**

This newly discovered group consisting of highly preserved mediators (from insects to mankind) participates in the innate immune response. Their role in defence and potential involvement in inflammatory diseases is currently under investigation.

- **Vasoactive amines**

Histamine, serotonin and kinins (bradykinins) are vasodilatory, increase the capillary permeability and facilitate smooth muscle contraction.

- **Complement proteins**

The complement system is an important part of the innate immune defence, because it is activated rapidly and is able to provide a powerful answer to infection through a cascade of reactions, amplifying the activity of several functions of the complement system. These functions include chemotaxis, opsonisation and lysis of bacteria. The complement system can be activated via different routes (the classical, alternative and lectin pathway), enabling the synthesis of, for example, opsonising fragments ($C3b$) or anaphylatoxins ($C3a$, $C5a$) that induce the release of histamines (figure 9).

- Coagulating proteins

Factor XII (Hageman factor) activates kallikrein that transforms kininogen into bradykinin (a vasoactive amine).

- Lipid mediators

Different lipid substances are produced and released by various cell types resulting in e.g. immune cell activation and chemotaxis (figure 10).

- Inflammatory proteins of hepatic origin (C reactive protein, serum amyloid A, α 1-antitrypsin, haptoglobin, fibrinogen, ceruloplasmins, and other acute phase proteins)

These proteins, that are produced during the acute phase of inflammation, can mediate pro- and anti-inflammatory effects and facilitate the removal of cellular waste.

- Cytokines

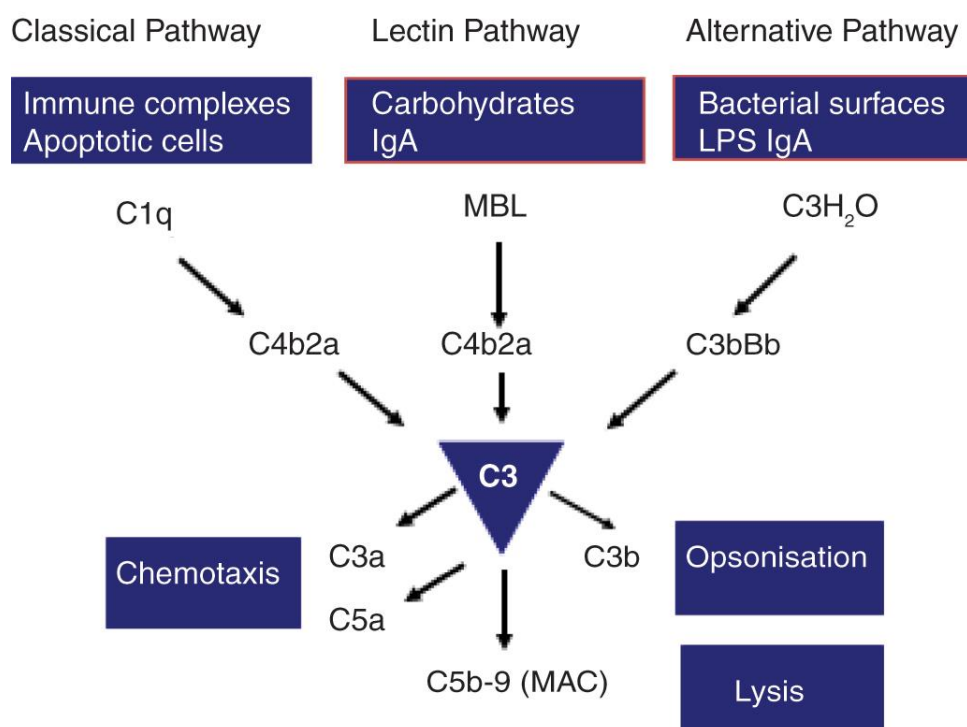

Many different cytokines, such as IL-1, IL-6 and TNF α can be released by various cell types rapidly after encounter with pattern recognition receptors (PRR)-activating microbes.

- Endogenous corticoids

This group, of which cortisol is the most important substance, consists of powerful anti-inflammatory agents that exert their action by means of different mechanisms, in particular the inhibition of pro-inflammatory cytokines.

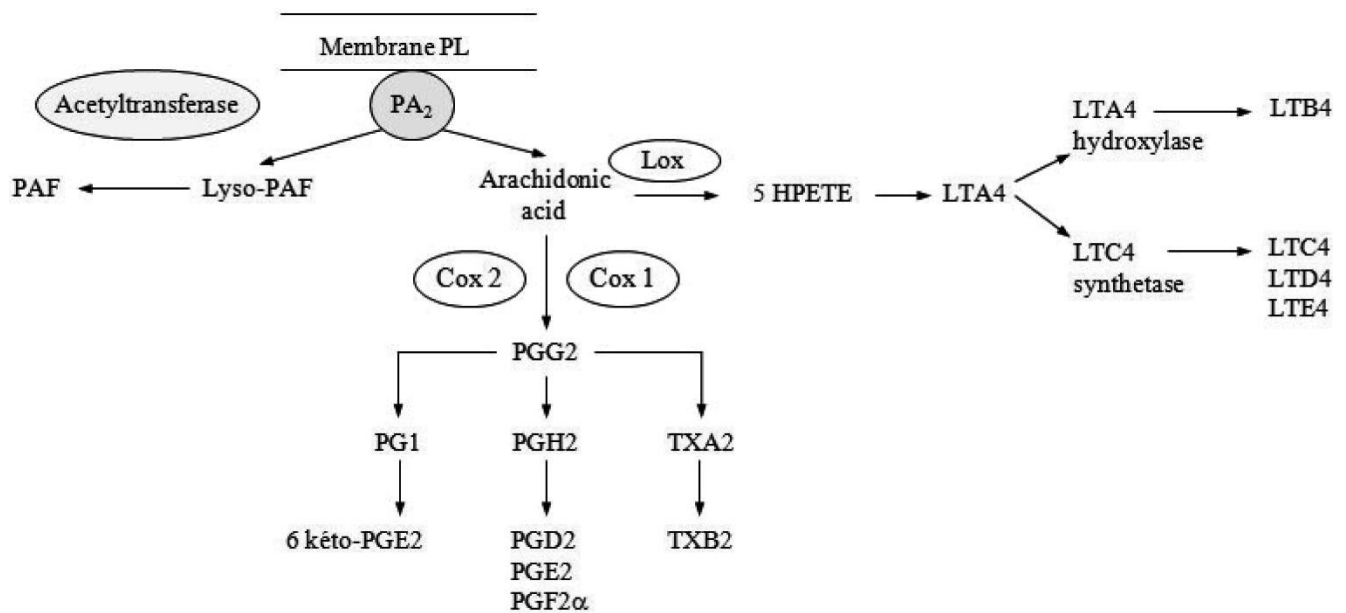

Figure 7 The complement system.

Background on complement activation

Furthermore, activated innate immune cells release mediators such as prostaglandins, nitric oxide, and pro-inflammatory cytokines and chemokines, that activate the surrounding stromal cells, attract infiltrating immune cells and induce a systemic inflammatory response (figure 8). These cytokines include TNF α , IL-6, IL-1, IL-23 and chemokines such as IL-8, MCP-1 (monocyte chemoattractant protein-1), IP-10 and MIP1 α and β , which will attract other inflammatory cells to the site of inflammation.

Figure 8 Inflammatory mediators derived from cell membrane constituents. *Cox, cyclo-oxygenase; Lox, lipo-oxygenase; LT, leukotrienes; PAF, platelet activating factor; PA2, phospholipase A2; PG, prostaglandin; PL, phospholipid; Tx, thromboxane.*

Inflammatory cells will migrate to the tissues, triggering the elimination of microbial agents, but also amplifying local inflammatory signals. These signals explain the clinical symptoms we recognise as pain, redness, swelling, heat and loss of function. The concerted attack on the infecting pathogen can induce collateral tissue destruction. Tissue degradation products together with alarmins and proteins released due to tissue stress (such as heat shock proteins) are also able to activate PRR on innate immune cells similar to PAMPs and induce these to clear cellular and tissue waste. These mediators are termed damage associated molecular patterns (DAMPs [Figure 6]). Often, this innate immune response suffices to clear a pathogen. Subsequently, innate immune mechanisms become active that resolve activated immune cells and repair damaged tissues.

However, many pathogens have evolved offense mechanisms that inhibit or skew innate immune defence responses that allow them to persist and infection to spread. This causes long-lasting infections, such as can be seen in young children and when patients do not receive antibiotic treatment. The adaptive immune system has evolved to combat these pathogens. Dendritic cells and the recently discovered innate-like adaptive immune cells, such as innate lymphoid cells (ILCs), play a key role in bridging the innate and the adaptive immune system. These cells become active as part of the early innate immune response against pathogens in a

tissue and are intimately involved in setting how the immune response evolves. Dependent on the type of pathogen specific PRR innate-like adaptive immune cells are triggered leading to the production of specific patterns of cytokines and chemokines. These cytokines and chemokines polarize the immune response towards more efficient killing of, for instance, intracellular or extracellular bacteria or intracellular viruses (polarization will be discussed below in more detail when discussing T cell subsets).

Following exposure to microbes, dendritic cells triggered through their PRR, undergo a process of maturation and migrate to the lymphoid organs where they become capable of activating T-lymphocytes. This requires a series of steps, the most important of these being the ingestion of the pathogen by phagocytosis, digestion into fragments and presentation of these fragments on their cell membrane major histocompatibility complex (MHC) molecules (encoded by human leucocyte antigen [HLA] genes). On the cell surface each MHC molecule displays a molecular fraction of a protein (i.e. a peptide), also called antigen, where it can be recognised by T cells. MHC class I is expressed on nearly all cells in the body and present peptide-antigens to CD8+ killer T cells, and MHC class II is expressed on professional antigen presenting cells, dendritic cells, B cells and macrophages and presents antigen to CD4+ helper T cells. Initially, presentation of antigen on MHC class I or II occurs mainly by dendritic cells to T cells in lymphoid tissues. Matured dendritic cells also deliver a second signal crucial to proper T-lymphocyte activation. This second signal is called co-stimulation and is provided through CD80/CD86-CD28 interaction, where CD80/86 molecules are expressed by the dendritic cells and CD28 by the T cell. Immature dendritic cells express far less CD80 and CD86 and hence cannot activate naïve T cells, but instead are thought to induce regulatory or anergic cells. Finally, dendritic cells polarize T cells towards a specific cell subset by production of cytokines. Antigen presentation by non-immune cells, macrophages and B cells to T cells occurs mostly later during an immune response (explained below). B cells in lymph nodes are also activated by antigens. In contrast to T cells, these either freely diffuse into the lymph nodes or are presented by macrophages or dendritic cells that capture and present antigens with non-MHC receptors.

4.2 Lymphocyte activation occurs in the lymph node, spleen and peripheral tissues

Peripheral lymphoid organs have multiple roles, since they:

- receive dendritic cells that have captured antigens in peripheral tissues;
- facilitate activation (both proliferation and differentiation) of T and B cells;
- enable these activated lymphocytes to spread to areas where the adaptive immune effector responses are required.

These functions explain the original organisation of these peripheral lymphoid organs.

4.2.1 What is the composition of the lymph node?

Lymph nodes are highly organised structures functioning as sites of convergence of an extensive system of vessels collecting afferent lymph fluid and cells from tissues and ultimately returning it to the blood via efferent lymphatic vessels (figure 9).

Figure 9 The 'anatomy' of the lymph node. Ag, antigen; BL, B lymphocyte; DC, dendritic cell; M, macrophage; TL, T lymphocyte.

- What cells arrive in lymph nodes?
 - Antigen presenting cells, that have captured antigen in peripheral tissues, such as the skin or gut, arrive at the lymph node through afferent lymphatic vessels.
 - Naïve lymphocytes traffic to the lymph node through the blood circulation.
- What happens in the lymph node?

Lymphocyte activation and cooperation are highly organised and tightly regulated events that are temporally and spatially coordinated in the lymph node. It requires the recognition of specific antigens presented by dendritic cells on their MHC by specific T cells and antigen recognition by specific B cells. Each T and B cell express unique antigen detecting receptors, which are termed the T and B cell receptor (explained further below). To increase the chance of antigen recognition T and B cells dynamically recirculate through lymph nodes, while antigen can be retained by lymph node dendritic cells for many weeks. Activation of naïve T-cells upon antigen-recognition, results in their expansion and ability to provide help to B-cells. This “help” is

required for expansion and maturation of B cells into antibody-secreting plasma cells. This is a tightly regulated process, and the interaction of activation-induced expression of molecules on T cells (eg, CD40L), with the corresponding counter-receptors expressed on B cells (eg, CD40), plays a pivotal role in the T–B cell interplay.

These processes are reflected in the lymph node architecture (figure 9). Thus, at any one time the lymph node may be made up of:

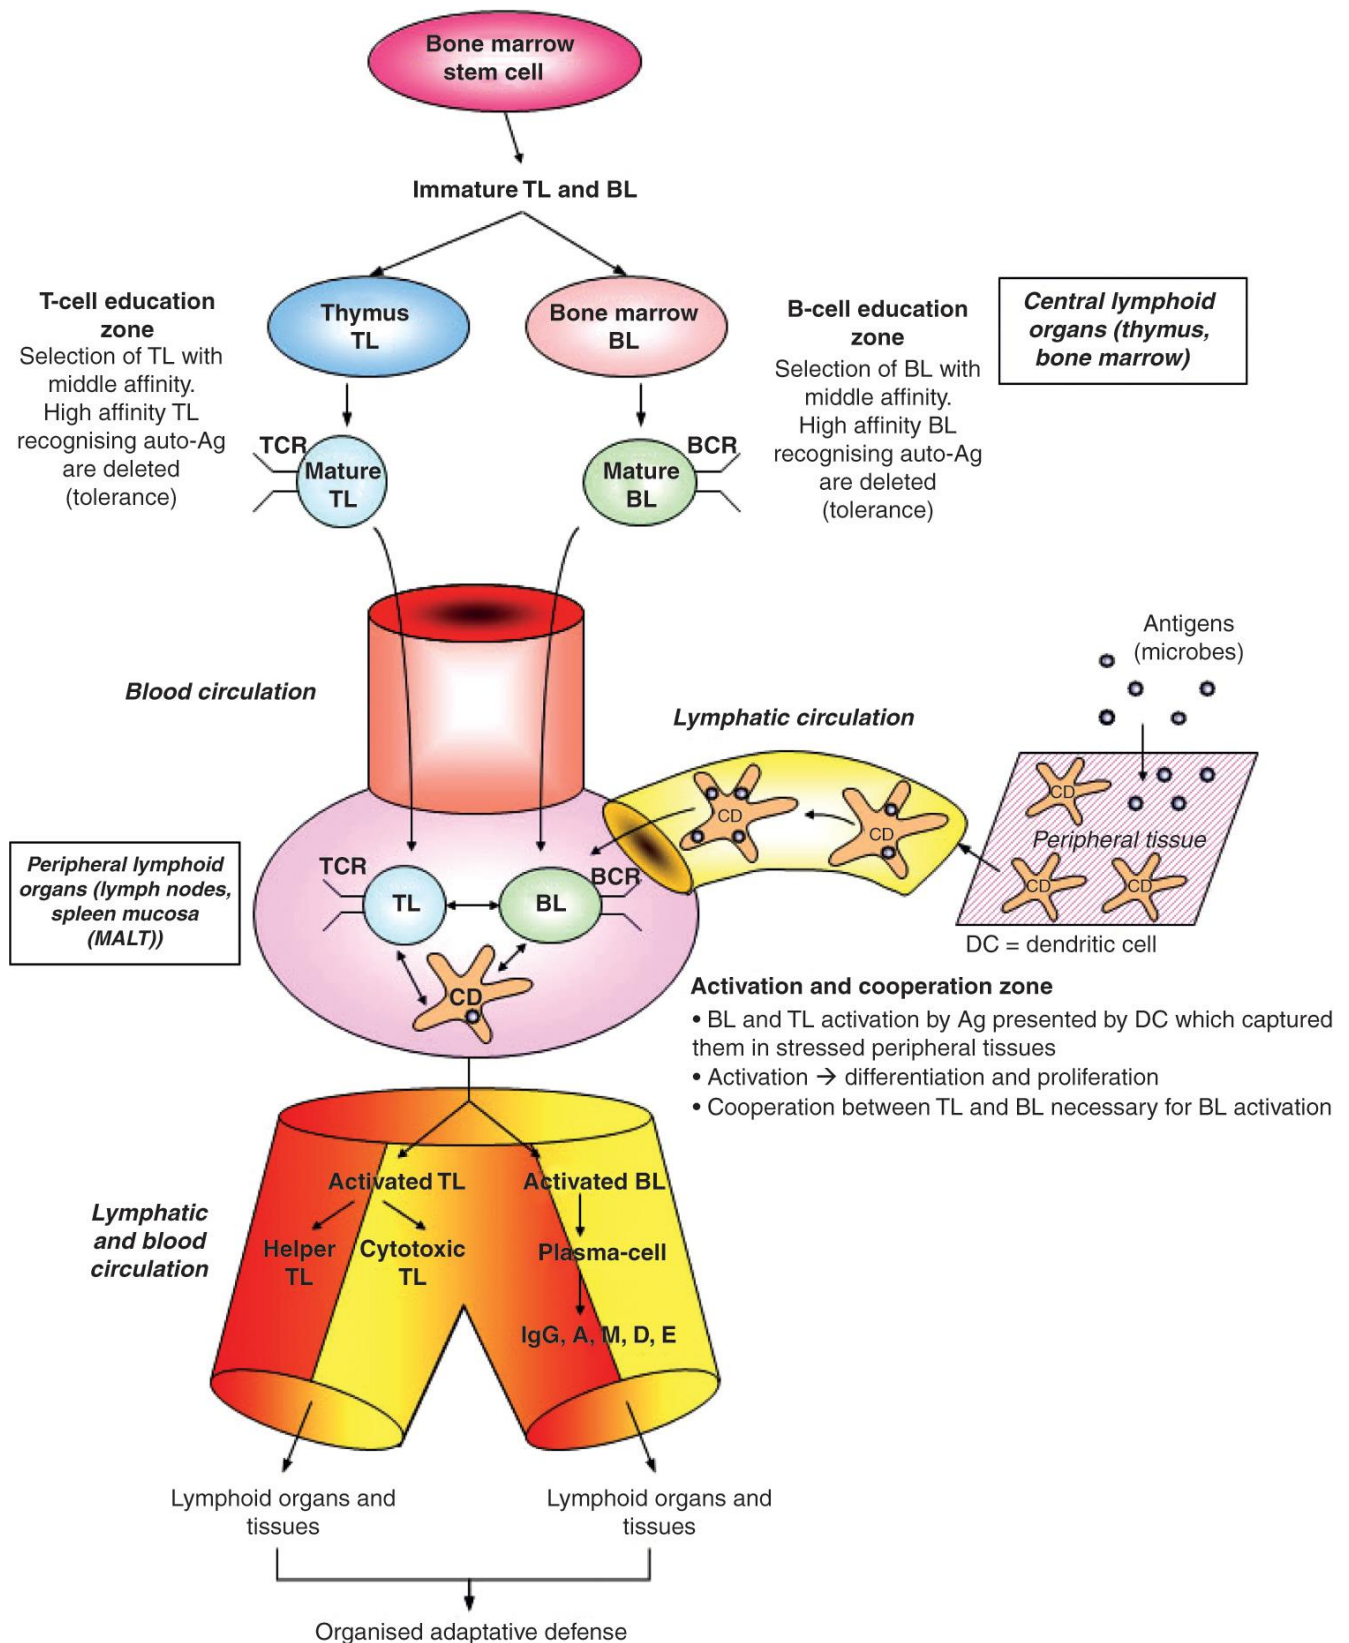

- a cortical zone where B cells recirculate to and may encounter antigens, resulting in proliferation (termed primary follicle);
 - a paracortical zone, where T cells recirculate;
 - B cell follicular structures that include germinal centres, in which B cells undergo intense proliferation, somatic hypermutation (explained below) and differentiation following encounter with specific antigen and T helper cells;
 - a marginal zone where B cells can be activated when in contact with specific B antigens, regardless of T cells;
 - a medullary zone consisting of macrophages and mature B cells that become antibody producing plasma cells.
- What are the consequences of lymphocyte activation, proliferation and differentiation?

Activated lymphocytes migrate through efferent lymphatic vessels into the blood circulation, via a main channel, the thoracic duct, which joins the systemic circulation at the left subclavian vein. These activated lymphocytes are able to migrate to peripheral tissues to participate in the immune response, as required (figure 10). Here in the inflamed tissue, lymphocytes can be further activated by MHC class I on tissue cells, leading to the elimination of e.g. virally infected cells, and by MHC class II on professional antigen-presenting cells such as macrophages leading to further control of infections

- What becomes of the lymphocytes that are not activated in the lymph node?

Those lymphocytes that are naïve (ie, they are not engaged by specific antigen) will either die or recirculate through efferent lymphatic vessels to repopulate peripheral lymphoid organs, where they may become activated upon antigen encounter.

Figure 10 Structural organisation of the lymphoid system. BCR, B cell receptor; BL, B lymphocyte; DC, dendritic cell; M, macrophage; MALT, mucosa-associated lymphoid tissue; TCR, T cell receptor; TL, T lymphocyte.

4.2.2 What is the role of the spleen?

The spleen is a lymphoid organ, with similar functions to lymph nodes, and a structure that includes lymphoid follicles. In contrast to lymph nodes, the antigens enter the spleen via the blood, more specifically via arterioles, to form a region called the white pulp. The white pulp comprises the periarteriolar lymphoid sheath (PALS) containing mainly T cells and a flanking B cell corona. As part of the immune response, germinal centres form at the interface between these T cell and B cell zones. Following activation, lymphocytes exit the spleen through the bloodstream. Although it is possible to remove the spleen without jeopardising life, the spleen does play a role in the immune protection against sepsis from polysaccharide encapsulated bacteria.

4.2.3 What is the role of lymphoid tissues associated with the mucous membrane?

Mucous membranes have a system that is particularly original and crucial for host defence, since these mucosal sites in the gut and lung form a massive surface area of tissue that is in direct contact with the environment. The lymphocyte infiltrate in these mucous membranes forms what is termed mucosa-associated lymphoid tissue (MALT). MALT exists at numerous sites, but is best characterised in the respiratory tract as bronchial-associated lymphoid tissue (BALT), and in the digestive tract as gut-associated lymphoid tissue (GALT), enriched in the tonsils, intestine and appendix. In the small intestine, antigens assemble together via a particular system comprising a network of epithelial 'multi-window' or 'M' cells, which trap antigens in the intestinal lumen. These antigens can then be presented to lymphocytes in the mucous membrane that form structures in special zones called Peyer's patches.

It is likely that lymphoid tissue of MALT contains more lymphocytes than the rest of the immune system. The MALT system functions like lymph nodes and the spleen, based on the principles of spatial interactions between the professional antigen presenting cells (dendritic cells) and lymphocytes. In contrast to lymph nodes and spleen, which may be considered 'persistent' secondary lymphoid organs, a particular characteristic of this MALT tissue is that it may appear and disappear depending on the environmental stimuli. It is now generally accepted that comparable lymphoid organisation, or lymphoid neogenesis, is observed in other tissues such as salivary glands or synovium. Under these circumstances, persistence of such structures accompany chronic immune pathological conditions such as Sjögren's syndrome and rheumatoid arthritis. Although relatively rare, malignant transformation has also been described in these tissues, leading to a group of conditions known as MALTomas or MALT lymphomas.

4.3 While lymphoid organs coordinate the generation of specific effector defence responses, they are also the sites of immune regulation

Immune regulation in the periphery, known as peripheral tolerance, is based on the induction, activation and expansion of specific subsets of T and B cells that exert regulatory properties. Their function serves to regulate and stop immune responses. The best characterised are T regulatory cells (Tregs), defined at least in part on the basis of the anti-inflammatory cytokines that they produce during an immune response (eg, IL-10 and transforming growth factor β (TGF β)). Defining the mechanisms whereby regulatory cells exert their suppressive effects on the activation and expansion of effector cells is a topic of great interest. Production of anti-inflammatory mediators such as IL-10 and TGF β are important, but cell contact dependent pathways also exist, which are less well defined.

5 The adaptive immune system in action

5.1 How are T cell effector functions initiated?

After infection of the body by a microorganism and presentation of microbial epitopes by a dendritic cell to T cells in lymphoid tissue, T cells that recognise the pathogen with their T cell receptor in a specific fashion will become activated and start dividing. The activation of T cells requires two successive signals:

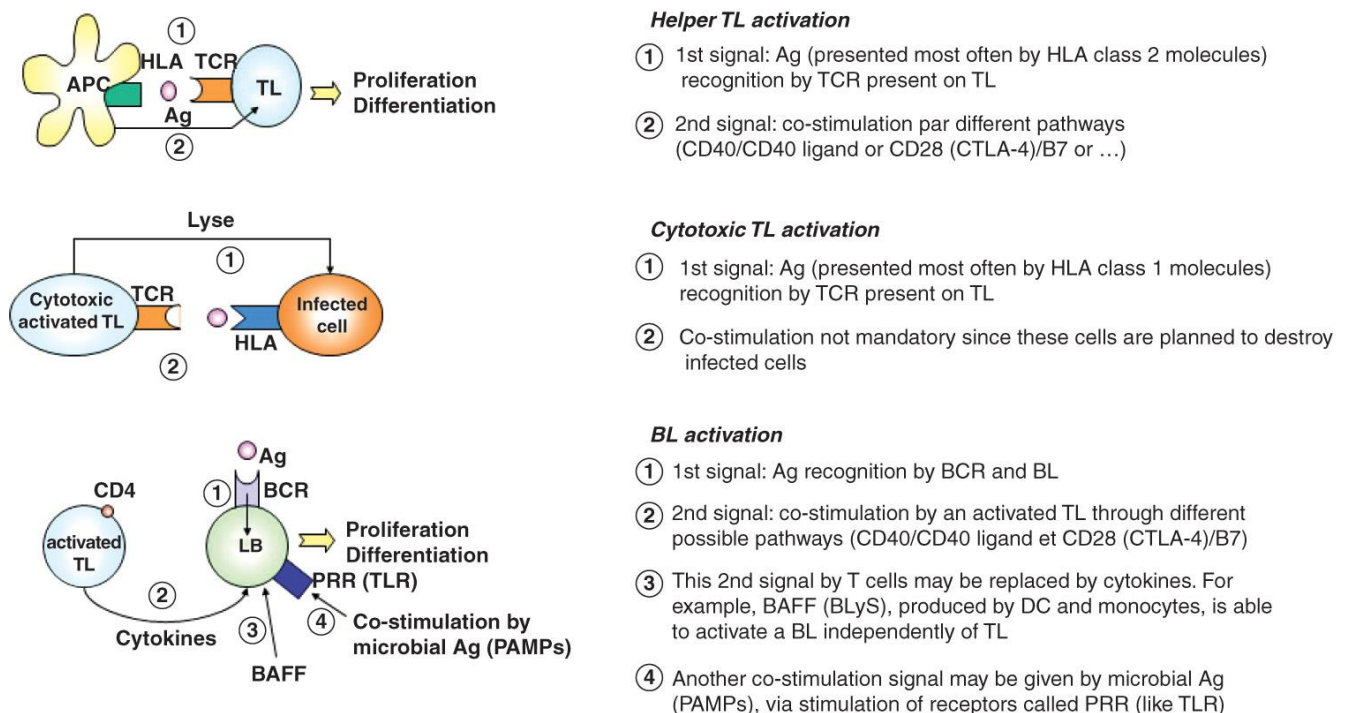

- The first signal is recognition by specific membrane receptors of the T cell. The receptor is called the T cell receptor (TCR)/CD3 complex, and is made up of variable antigen recognition subunits (TCR α and β chains, or TCR γ and δ chains), and invariant signal transducing units (CD γ , δ , and ζ chains). The TCR recognises a complex of antigenic peptide bound to MHC class I or II molecules expressed on the surface of antigen presenting cells (figure 11). MHC class I molecules present peptides from proteins synthesised in the cytosol such as viral peptides, and are recognised by CD8+ T cells. Class II molecules, recognised by CD4+ T cells, mostly display proteins that are present in intracellular vesicles that originate from the phagocytosis of pathogens (figure 11).
- While the overall structure of MHC molecules is rather similar, the antigen binding domains of MHC molecules are highly variable between individuals. This variation in MHC sequence (particularly within the peptide binding groove and pockets that accommodate antigen peptide amino acid side chains), permits the binding of a wide range of antigenic peptides. This means that different HLA molecules (encoded by different HLA genetic variants) present different fragments of a particular peptide to T cells. This process of recognition of an MHC/peptide complex by T cells is essential since T cells become activated if they recognise their matching antigen presented by an MHC molecule. Therefore, this antigenic specific response is said to be 'restricted' by the host MHC molecules. This genetic variability results in various protection and susceptibility to infections between individuals, but also variability in susceptibility to autoimmune diseases.

- TCR signals can be terminated by inhibitory receptors (eg CTLA4, PD-1).

The manner of activation of T cells by epitopes and co-stimulatory signals and cytokines delivered by antigen-presenting cells determines the specific T cell subset into which the cell will differentiate. This is termed polarization. As mentioned, CD8+ cytotoxic T cells are activated by MHC class I presented peptides and kill virus infected cells. The CD4+ helper T cell subsets are activated by MHC class II presented peptides and specific dendritic cell cytokines and have diverse functions.

T cells with helper function are, as a rule, CD4+ T cells; helper function refers to cytokine mediated activities on a range of cell targets, including not only B cells, but also cytotoxic CD8+ T cells, macrophages and granulocytes. Th cells come in different subsets (Th1, Th2, Th17 and Treg cells) that are generated from naïve precursor T cells. Over the years, a growing number of CD4+ T cells subsets have been described (figure 12), having been defined initially in the mouse based on cytokine profiles through the pioneering work of Mosmann and Coffman, first reported in 1986:

Figure 11 Lymphocyte activation. Ag, antigen; APC, Ag presenting cell (DC, macrophage, LB); BAFF, B cell activating factor; BCR, B-cell receptor; BL, B lymphocyte; BLyS, B lymphocyte stimulator; DC, dendritic cell; HLA, human leucocyte antigen; PAMPS, pathogen-associated molecular patterns; PRRs, pattern recognition receptors; TCR, T cell receptor; TL, T lymphocyte; TLR, Toll-like receptor.

- Th1 cells function to activate macrophages (M1) in ways that enhance microbial killing. This includes intracellular infections, such as Mycobacterium and Listeria species, that are not eliminated adequately by the innate immune defence. In fact, macrophages phagocytose mycobacteria in vesicles, which cannot fuse with the macrophage lysosomes, where they would be destroyed by enzymes and lysosomal antibacterial

proteins. Th1 cells are capable of inducing fusion of macrophage vesicles with lysosomes by activating the macrophages through synthesis of cytokines, such as interferon γ (IFN γ) (figure 13).

- Th1 cells are characterised by the profile of cytokines they produce (IFN γ), and they also release chemokines, which attract other macrophages that contribute to the inflammatory immune reaction. Th1 cells also contribute help for B cells and direct the production of specific IgG isotypes that promote host defence to intracellular pathogens. Th1 cells play key roles in autoimmune diseases and syndromes associated with chronic infection.
- Th2 cells have evolved to participate in responses against parasitic infestation through the promotion of IgE antibodies that neutralise antigen, and through promoting mast cells and eosinophils. By secreting cytokines such as IL-4, IL-5 and IL-13, they provide help for B cells to produce antibody isotypes such as IgG4 and IgE. Th2 cells play key roles in atopic and allergic disease.
- Th17 cells have been identified more recently, based on their expression of IL-17A and F, and IL-22. In man, they are thought to be generated in the context of cytokines that include IL-1, IL-23, IL-6 and TGF β . Current thinking suggests that they have evolved to participate in host defence against fungal infections, such as *Candida* as well as extracellular bacteria. IL-17 is a potent chemoattractant for neutrophils, so may contribute to the early infiltration of polymorphs to sites of infection. Based on studies in the mouse, Th17 cells contribute to organ specific autoimmunity, including inflammatory arthritis and demyelinating disease.
- T helper follicular cells (TFH) likely represent a population of T cells which, in lymphoid tissues together with follicular dendritic cells, play dominant roles in the selection of B cells in germinal centres. Their origin is not fully understood.
- Specific populations of CD4⁺ T cells exert immunosuppressive or regulatory function. These are collectively known as regulatory T cells, or specifically Tregs. An extensively investigated subset is CD4⁺ CD25⁺ and expresses the master transcription factor FoxP3 (box 2). Other regulatory T cell populations, such as Th3 and Tr1 cells play a variable role in various body compartments. Tregs are necessary to maintain homeostasis of the immune system, particularly by preventing the activation and expansion of self-reactive lymphoid populations.

While the assignment of specific cell lineages is an attractive model, it is likely that there remains much plasticity and reciprocity between T cell subsets *in vivo*.

After T cells are activated by epitopes, proliferate and differentiate into a specific T cell subset in lymphoid tissue after which they are called memory T cells. They may activate B cell partners in lymphoid germinal centres. Furthermore, they leave the lymphoid tissue as effector memory T cells, mediated by sphingosine 1-phosphate. It is likely that the nature of dendritic cell activation determines the profile of integrins and chemokine receptors expressed on the T cell that permits the cell to home to the appropriate infected tissue. Adhesion (mediated by rolling, chemo attraction and firm arrest) to microvascular endothelial and migration

into tissues is a highly regulated process mediated by selectins, chemokines and integrins, such as LFA-1 and VLA-4. At the site of infection they exert their effector function that result in enhanced innate immune cell function. After clearance of the infection memory T cells persist in blood and various body compartments. Memory T cells together with memory B cells and antibodies enhance and rapidly amplify innate immune responses when similar micro-organisms infect the body at later time points (adaptive immunological memory). In adults most adaptive immune responses are directed by memory TB and T cells.

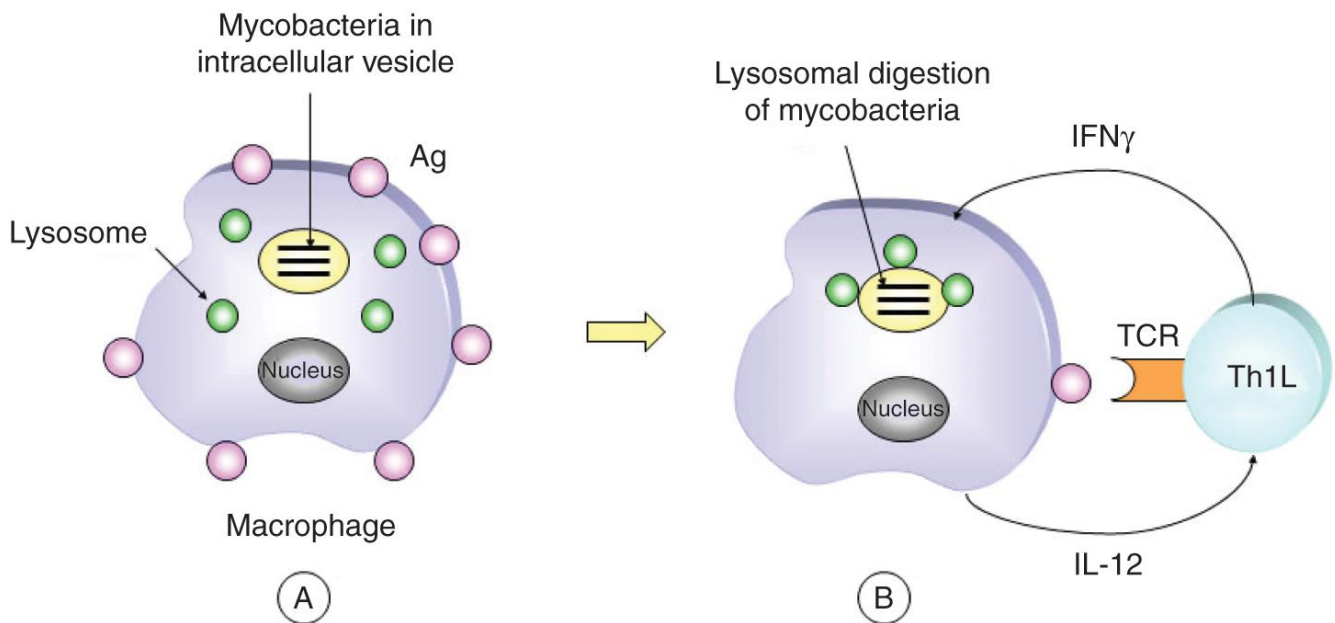

Figure 13 Mechanism of defence against an intracellular mycobacterial infection. Ag, antigen; IFN, interferon; IL, interleukin; TCR, T cell receptor; Th, T helper.

5.2 What are the effector functions of B cells?

5.2.1 Antibodies

An important part of the adaptive immune system combatting invading pathogens is mediated by antibodies (humoral immunity). Antibodies are glycoproteins produced by B cells. Antibodies bind to the molecules of pathogens that provoked the immune reaction and are able to activate various other molecules of the immune system (such as the complement system) in order to eradicate the pathogen.

Binding of an antibody to a virus can, for example, prevent the infection of other cells. At the same time, the virus is marked for destruction by phagocytes and the complement system. Antigen recognition and effector function are structurally separated within the antibody molecule; one part binds specifically to the antigen, whereas the other end of the molecule is involved in recruiting immune effector systems. The antigen-binding part is highly variable between different antibodies and is therefore also known as the variable part or the V-region of the antibody. This variability of antibodies allows the antibody system to bind to many different antigens, where one antibody is always specific for one antigen. The region of the antibody that is involved in the 'recruitment' of effector functions of the immune system is rather constant and hence this region is called the constant region or C-region. The membrane-bound form of an antibody, which is present on naïve and memory B cells, cannot recruit effector mechanisms as it is anchored in the B cell membrane (termed the B cell receptor). It is, however, involved in the activation of the B cell after it has bound antigen through its

variable part. This leads to proliferation of this B cell (a process termed clonal expansion) and the production of specific antibodies that can be measured in serum of individuals.

Antibodies can exert several different effector functions: neutralisation of viruses or toxic products from pathogens, complement-mediated lysis of microorganisms, opsonisation of microorganisms for phagocytosis and antibody-dependent cellular cytotoxicity (ADCC). In case the antibody is directed against molecules expressed by cells (for example, rituximab which recognises CD20, a molecule expressed by B cells) it can also lead to killing of cells through complement-mediated lysis or ADCC. ADCC can be mediated by several immune cells, such as NK cells to kill virally infected cells, or granulocytes to combat parasites. Recognition of antibody–antigen complexes in general and ADCC in particular is dependent on the recognition of the immune complex by specialised receptors on immune cells—the Fc-receptors (which recognise the constant region (the Fc-region) of antibodies). To which extent an antibody can recruit these different immune effector functions depends on its type of constant region that can vary in subclass (or isotype) (ie, IgM, IgD, IgA1, IgA2, IgG1, IgG2, IgG3, IgG4 and IgE).

5.2.2 B cells

After invasion of the body by a microorganism, and presentation of microbial antigens to B cells in lymphoid tissue, B cells that recognise the pathogen with their B cell receptor in a specific fashion will become activated and start dividing. These B cells differentiate subsequently to plasma cells that produce and secrete antibody. The antibodies produced by the offspring of a single B cell (a B cell clone) have the same specificity as the membrane-bound antibody receptor that is expressed by the precursor of that given B cell clone. The production of antibodies, that can bind and neutralise pathogens and their toxic products in the various body compartments, is one of the most prominent functions of B cells as part of the adaptive immune system.

Mature B cells are activated after antigen recognition in lymphoid organs. After initial activation of mature B cells, short-lived plasmablasts that are responsible for the production of the first wave of antibodies are immediately formed (figure 14). These antibodies circulate to the site of infection and enhance microbial killing through their various effector functions. Next to the formation of relatively short-lived plasmablasts, also memory B cells are formed recognising the same inciting antigen. In general, memory B cells against T cell dependent antigens have undergone isotype switching (ie, express another Fc region, most often an IgG- instead of an IgM-tail) and express a mutated immunoglobulin variable region. The latter is a result of a process called somatic hypermutation and results in an increase in avidity of the overall antigen-specific B cell response as it selects for (memory) B cells that have been able to increase the strength of antigen recognition by the B cell receptor. Both isotype switching and somatic hypermutation result in the formation that improve microbial killing in prolonged infections. Activated B cells can also migrate to sites of inflammation. Here they can then also differentiate into plasmablasts, produce and secrete the required antibodies to combat the

infection locally. B cells also have other functions that contribute to the immune response. They contribute to activation of T cells at the site of infection since the B cell expresses HLA and co-stimulatory molecules and so function as an antigen-presenting cell. B cells also produce abundant pro- and anti-inflammatory cytokines, as well as chemokines.

Furthermore, memory B cells can differentiate further to long-lived plasma cells. These cells can migrate to special niches in the bone marrow where they keep on secreting antibody for years. Also memory B cells persist after clearance of the infection similar to memory T cells. The size of the effector memory T and B cell pool during and persistent memory pool after infection is determined by growth factors such as IL-7 and B cell activating factor (BAFF) for T cells and B cells, respectively. Together with the antibodies secreted by long-lived plasma cells, memory B and T cells form adaptive immunological memory. It is this phenomenon that forms the rationale for vaccination.

The human immune system has evolved several hurdles to prevent occurrence of autoimmunity. These are called 'tolerance checkpoints'. A crucial checkpoint is that, as explained above, for optimal B cell differentiation, antibody production and memory formation, most B cells need help from CD4⁺ T helper (Th) cells. CD4⁺ Th cells can give an additional signal to B cells via the production of cytokines such as IL-4 and direct cell–cell contact, required for activation of the enzymes involved in somatic hypermutation and isotype switching. Likewise, the help of T cells is often also required for the formation of memory B cells. Thus, by recruiting the help of T cells, B cell responses can mature and remember. In order to provide help to B cells, CD4⁺ Th cells need to see antigen in the context of HLA molecules. B cells that acquire antigen through their membrane-bound antigen receptor (the membrane-bound antibody) can take up the antigen inside the cell, digest it, and present it subsequently in the context of HLA class II molecules on their cell surface for recognition by T cells. Only T cells recognising this antigen become activated and can provide help to this particular B cell. There, high affinity antibodies, memory B cells and IgG antibodies against a particular antigen will only be formed in case B cells and T cells recognise the same antigen/pathogen. This is often the case when a pathogen invades the body because such a pathogen is 'foreign' to the body. Therefore, there is a relatively high chance that both a B cell as well as a T cell are present in the body that can recognise the invading pathogen. In contrast, however, a B cell that would recognise a self-molecule is far less likely to be able to attract helper activity from CD4⁺ Th cells, as these T cells are likely not present (and vice versa). Therefore, the requirement of T cell help for the generation of optimal antibody responses is an additional protective measure against the development of (B cell mediated) autoimmunity.

Figure 14 B cell differentiation.

6 How is the immune system measured?

6.1 Detection of humoral immune responses

In clinical practice, analysis of immunoglobulin levels (abnormal in autoimmune conditions, paraproteinaemias, globinopathies and primary immune deficiencies) has become routine. Identification of ongoing, recent or past infections (bacterial or viral) and evaluation of vaccine responses is also common practice. In addition, immunoassays have, for many years, become central to the repertoire of clinical laboratories, providing key diagnostic information for a wide range of conditions including organ specific autoimmune diseases, connective tissue diseases, the vasculitides and rheumatoid arthritis. Dynamic assays of B cell function are, to a large extent, the domain of the research laboratory.

Examples of the more common assays employed to evaluate components of humoral immunity include:

- quantitative analysis, where the amount of immunoglobulin protein is determined (adult values): IgG 7–15 g/l, IgD 0–150 mg/l, IgA 0.6–4 g/l, IgE 3–190 U/ml, IgM 0.6–3 g/l;

- serum electrophoresis, providing a global picture of immunoglobulin levels in the context of other abundant serum proteins such as albumin and α -macroglobulin;
- serum or urine immunofixation to confirm the presence of a monoclonal immunoglobulin when it is suspected by the presence of a peak on electrophoresis;
- detection of cryoglobulins;
- enumeration and phenotyping of B cells, according to expression of B cell lineage markers CD19 or CD20 (eg, evaluation of therapeutic B cell depletion; normal range 200–1250/mm³);
- analysis of light chain subunits (2/3 kappa and 1/3 lambda)—these proportions may be deranged in autoimmune disease and haematological malignancies;
- functional analysis, including studies of antigen specific responses and evaluation of neutralising titres (eg, to influenza, pneumococcal antigens and tetanus toxin), and B lymphoblast transformation (in response to mitogens; of limited value in the clinical setting).

6.2 Evaluation of cellular immunity

A family history may provide clues as to the possibility of cellular immune deficiencies. Although rare, these lead to susceptibility to specific infections, manifest in early life, and may be X-linked. Neoplastic complications and, paradoxically, autoimmunity also may be a manifestation of an immune defect.

Components of cellular immunity are commonly evaluated by:

- enumeration and phenotyping of total T cell numbers, and T cell subsets by flow cytometry. Normal values in adults are: total number of lymphocytes (CD45) 1500–5000/ml, CD3+ 1400–4000/ml, CD4+ 600–2500/ml, CD8+ 350–1500/ml, CD4/CD8 ratio 0.98–3.20, NK cells (CD56+ CD16+) 150–1000/ml;
- evaluation of antigen specific responses in vivo, such as following intradermal injection of tuberculin or candida antigens. This is also known as a delayed type hypersensitivity reaction.
- in vitro proliferative responses to antigens (candida, tuberculin/PPD (purified protein derivative), tetanus toxin) or to mitogens (phytohaemagglutinin, concanavalin A, pokeweed mitogen) or following cross-linking of the TCR/CD3 complex with anti-CD3, with or without anti-CD28 for co-stimulation.

6.3 Detection of innate immune responses

There are few assays employed in routine practice that provide a robust or dynamic analysis of innate immunity. The following could be viewed as screening assays that may provide important clues:

- functional assessment of complement activity (CH50). CH50 (total haemolytic complement) measures the lysis of sheep red blood cells sensitised with rabbit IgM, by a patient's serum. All nine components of activation of complement by the classical pathway are necessary to achieve a normal CH50. If CH50 is abnormal, specific tests can be used to find the absent component;

- evaluation of complement components and breakdown fragments;
- quantitative enumeration, by flow cytometry, of innate immune cells: monocytes, neutrophils, eosinophils, basophils and mast cells;
- in vitro assays of phagocytosis.

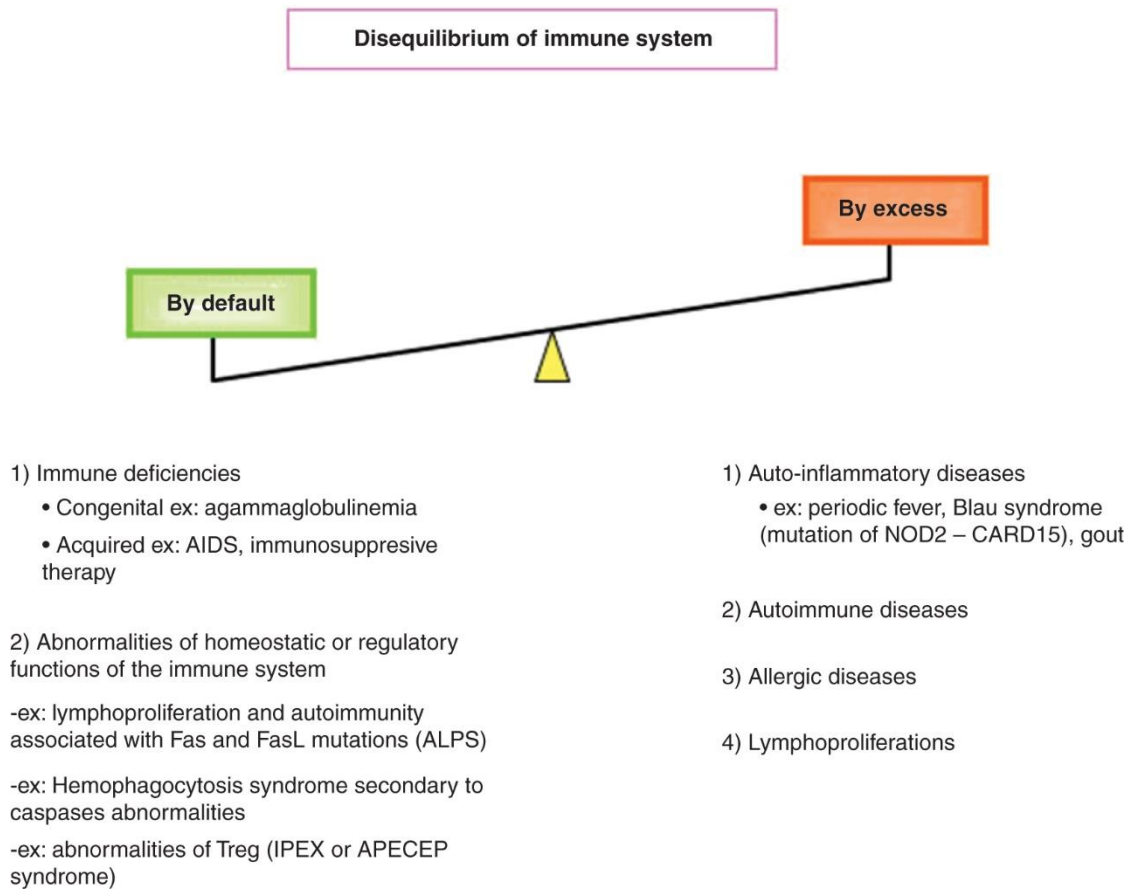

6.4 New techniques

While many studies of immune function lie more within the scope of the research laboratory, new technologies now permit the unbiased and systematic evaluation of large numbers of analyses such as gene variants (genomic techniques such as SNP Chips), gene expression/mRNA (transcriptomics, applying DNA microarrays) and proteins (proteomics, applying medium to low density protein arrays; protein analysis using bead-based protein arrays). Determination of TLR-induced cytokine production by monocyte subsets is just one example. Analysis of cells at a single cell level, by flow cytometry (pioneered by Herzenberg, Stanford, California, USA), are likely to continue to play a major part in immune phenotyping, as this approach becomes more applicable in the clinical setting. Flow cytometry is highly adaptable, and can analyse mixed populations of live cells, accommodating assays of cell protein expression, cell division, expression of secreted proteins as well as analysis of T cells specific for self, foreign and tumour antigens (using tetramer technology), and analysis of the state of activation of specific signalling pathways (PhosphoFlow). Nonetheless, cell-based functional assays remain a challenge.

7 Aberrations of immunity

Dysregulation of the immune response is a key element that underpins pathogenicity of multiple immune and inflammatory diseases (IMIDs). Taken at the most fundamental level, there are two broad categories of disease that reflect the two extremes of immune dysregulation (figure 15). The first group is characterised by deficiencies of the immune system. The second group of diseases includes those in which there are features of an excessive, overactive or inappropriately persistent immune response.

Figure 15 The main diseases linked to a dysfunction of the immune system. *ALPS*, autoimmune lymphoproliferative syndrome; *APECEP*, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; *IPEX*, immune dysfunction, polyendocrinopathy, and enteropathy, X-linked.

7.1 Immune deficiencies

7.1.1 Inherited immune deficiency syndromes

The prototype immune deficiencies, first described in 1952, are inherited (the majority being monogenic and recessive, with a subset being X-linked), of which there are >100 in man. Gene knockout technology in rodents has added greatly to our knowledge of immune deficiencies. Each of these forms is characterised by a specific clinical disease entity, imposed by the genetic anomaly and the cellular or molecular component of the immune system that is affected. A few examples are included below.

- Deficiencies in the adaptive immune system, arising commonly through defects in lymphocyte development, may lead to a complete lack of T and/or B cells (severe combined immune deficiency—SCID). SCID arises due to specific deficiencies in adenine deaminase (ADA), purine nucleotide phosphorylase (PNP), the cytokine receptor common γ chain subunit or enzymes involved in DNA repair. More selective defects, such as those that target humoral deficiencies (Bruton's X-linked agammaglobulinaemia, due to a deficiency of protein tyrosine kinase—Btk—required for B cell development) are defined by the absence of B cells, low levels of immunoglobulin and impaired clearance of extracellular bacteria. Subjects with X-linked hyper-IgM

syndrome have normal numbers of T and B cells, but have high IgM levels and generate limited levels of Ig isotypes other than IgM and IgD in response to pathogens. The defect is in CD40L expression, which is normally expressed on T cells, as opposed to B cells which express CD40. This defect is explained by the CD40ligand-CD40 interaction which is crucial in the help to B cells given by CD4⁺ Th cells. In case a defect in CD40L is present, the antibody response is severely affected in its ability to undergo somatic hypermutation and isotype switching. Hence a reduced level of IgG is present which, in part, is compensated by higher IgM levels. The hampered antibody response makes patients susceptible to infection with extracellular bacteria but also to opportunistic organisms such as *Pneumocystis carinii*.

- Innate immune deficiencies also exist, in particular anomalies of phagocytosis or phagocyte function (eg, chronic granulomatous disease), defects in cytokines and their receptors, and deficiencies of specific components of complement. Complement deficiencies cause syndromes associated with persistence of immune complexes, which activate phagocytes, causing inflammation and tissue (eg, renal) damage. Recently, more specific deficiencies of some molecules belonging to the innate immune system have been described, such as those that target elements of receptor signalling pathways (eg, IRAK4 mutations, leading to pneumococcal infections).

Immune deficiencies are characterised by a fundamental defect in the host response to specific pathogens leading to chronic or recurrent infections; before the antibiotic era, it is likely that most individuals would have died from these infections during infancy. This is especially true of those defects in innate immunity, since defects in the adaptive immune system, with the possible exception of the most severe forms, are in general better tolerated. For example, defects in the IFN γ pathway predispose to recurrent infection with intracellular pathogens such as *Mycobacterium* and *Listeria* species. Paradoxically, immune deficiencies are commonly complicated by autoimmune disease (in particular thyroid autoimmunity and haemolytic anaemia), as well as lymphoproliferative or neoplastic syndromes (associated with persistent viral infection, such as Epstein-Barr virus (EBV)).

7.1.2 Acquired immune deficiencies

The most famous example of acquired immune deficiencies is AIDS. First reported in 1981, AIDS is caused by the human immunodeficiency virus that destroys the T cells, dendritic cells and macrophages, gaining access to these cells through high affinity interactions with cell surface receptors such as the CD4 co-receptor and chemokine receptors (eg, CCR5). There are other acquired deficiencies that arise as a consequence of immunosuppressive treatment (high dose glucocorticoids, cell depleting biological therapies, therapies used to maintain tolerance to tissue allografts), that increase the risks of infection and, in some very particular situations, of neoplasia.

7.1.3 Conditions determined genetically (through Mendelian inheritance) may lead to loss of homeostatic equilibrium in the immune system

These conditions are often classified as immune system deficiencies, but they are manifested clinically by signs and symptoms ordinarily attributable to lymphoproliferative and autoimmune syndromes. The conditions are characterised by constitutional deregulation of apoptosis that leads to a homeostatic deficiency of the immune system. Examples include:

- Lymphoproliferative syndromes coupled with autoimmunity (also known as the autoimmune lymphoproliferative syndrome—ALPS). This group of diseases is characterised by genetic mutations in pathways promoting cell death—specifically apoptosis. The prototype ALPS arises through loss of expression/function mutations in the Fas receptor or its ligand, which leads to the inhibition of apoptosis and therefore persistence of peripheral lymphocytes. Affected individuals develop autoimmune symptoms, associated with lymphoproliferation and expansion of a subset of mature $\alpha\beta$ TCR T cells that lack CD4 or CD8 (double negative T cells). Variants of this syndrome have led to a better understanding of the role of apoptosis in maintaining immune homeostasis.
- Haemophagocytic syndromes, which are also the consequence of genomic anomalies that target caspases (enzymes that participate in intracellular death receptor signalling pathways).
- APECED syndrome (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome), an autoimmune T cell dependent polyendocrinopathy that targets the parathyroid, thyroid, adrenal and pancreas endocrine glands. This syndrome is the consequence of a genetic deficiency of autoimmune regulator (AIRE), a transcription factor involved in thymic expression of self-antigens that, when presented in the context of HLA class I or II, regulate the selection (negative selection or deletion) of autoreactive T cells during T cell development in the thymus.
- IPEX syndrome (immune dysregulation polyendocrinopathy-enteropathy X-linked) is an autoimmune T cell dependent disease that targets the endocrine system and intestines. This syndrome is linked to a genetic defect of Foxp-3, the master transcription factor of CD4⁺ CD25⁺ regulatory T cells.

7.2 Excessive immune activity

In the context of conditions associated with a pathologically overactive immune system, one might consider three broad groups of conditions, occurring with varying frequency.

7.2.1 Auto inflammatory syndromes

These inherited diseases are characterised by persistent, systemic, chronic inflammatory responses. These are monogenic and arise through poorly understood aberrations of inflammatory signalling pathways. These

syndromes are discussed in more detail in a subsequent module. Briefly, there are two groups of auto inflammatory syndromes:

- Recurrent hereditary fevers that comprise familial Mediterranean fever (or periodic disease), the hyper IgD syndrome and other diseases, such as periodic syndromes associated with cryopyrin (called CAPS for cryopyrin-associated periodic syndrome), Muckle-Wells syndrome, cold urticaria and CINCA or the TRAPS syndrome (a syndrome related to the mutations of the TNF receptor). These diseases are considered as inherited disturbances of the innate immune response.
- The other group of inflammatory diseases comprises certain forms of Crohn's disease, Blau's syndrome and, in all likelihood, other related granulomatous diseases. In these diseases, mutations of subunits of the inflammasome (an intracellular pathway that processes responses to the IL-1/IL-18 family of cytokines, as well as endogenous and exogenous stimuli), including the NOD2/CARD15 gene, lead to an abnormal cellular response to bacterial components. (The inflammasome is discussed further in the 'in-depth discussion'.) These diseases are also considered as inherited disturbances of the innate immune response. Excess production of uric acid, and precipitation to form urate crystals, may stimulate similar intracellular pathways leading to the inflammatory syndrome we recognise as gout.
- The mechanism of other auto inflammatory syndromes, such as adult Still's disease or PFAPA syndrome (which associates periodic fever, mouth ulcer, pharyngitis and cervical adenopathy), remains unknown, but may turn out, at least in part, to be inherited polygenic disorders. It is likely that in the years to come, we will discover numerous other auto inflammatory diseases, thus permitting re-classification of groups of known diseases, such as juvenile idiopathic arthritis.

7.2.2 Autoimmune diseases

Autoimmune diseases such as type I diabetes and rheumatoid arthritis are most likely caused by a response of the cells of the adaptive immune system (ie, T cells and B cells) to tissue of the host. It is, therefore, no surprise that in many autoimmune diseases auto-antibodies are found that can be more or less specific for a given disease. Also an association with the HLA system is often found, indicating that T cells are involved in the process leading to disease. Because B and T cells can form memory cells, and because the autoimmune response is directed against an antigen expressed by the person's own body, it is often difficult to cure autoimmune diseases such as type 1 diabetes and rheumatoid arthritis. The cause of most of the autoimmune diseases is not known but they are likely to arise through multiple mechanisms, some of which are shared across disease states. (Pathogenesis of several specific autoimmune diseases will be discussed in the following chapters.)

7.2.3 Lymphoproliferative disease

These syndromes can also be viewed as a consequence of excessive function of the immune system. This excess may be related to the deregulation of an elementary mechanism, such as apoptosis, as well as to chronic stimulation that may arise through persistent infection (eg, EBV infection). Examples include:

- Autoimmune diseases (eg, Sjögren's syndrome) in which there is an increased incidence of B cell lymphoma considered to be the result of chronic immune stimulation linked to persistent antigenic stimulation. Initially, this stimulation could be induced by an environmental agent as demonstrated by the example of lymphoma that complicates cryoglobulinaemia linked to the hepatitis C virus.
- ALPS, a rare but extreme example of genetically determined defects in immune homeostasis as a result of impaired apoptosis. There are other examples, such as follicular lymphoma, in which translocation (t14-18) leads to deregulation of the expression of Bcl-2, an anti-apoptotic gene. Therefore, in these two situations, the 'malignant' lymphocytes proliferate since the immune system no longer eliminates them.

7.2.4 Allergic and atopic inflammation

These conditions are excluded from this review, but they form a particularly important and common field.

8 Therapeutic agents as molecular scalpels for dissecting disease pathways

Increased knowledge of the immune system has underpinned the development of new immunomodulators such as 'biological' therapies, in particular, monoclonal antibodies and fusion proteins that inhibit the function of inflammatory mediators. These agents have become molecular scalpels for studying disease pathways.

Good examples include:

- the inhibition of pro-inflammatory cytokines, such as TNF α , IL-1 and IL-6 by monoclonal antibodies, soluble receptors or receptor antagonists (eg, infliximab, adalimumab, tocilizumab, etanercept, anakinra). These cytokines are produced in large quantities by both innate and adaptive immune cells in the response to various triggers and are therefore applicable in a broad spectrum of auto inflammatory and autoimmune disease;
- the use of an agent (such as the monoclonal antibody rituximab) that is capable of depleting populations cells such as B cells through recognition of lineage specific surface molecules such as CD20;
- the interruption of interaction between antigen presenting cells and lymphocytes by means of an inhibitor of co-stimulatory molecules, such as abatacept (CTLA4-Ig);
- the application of inhibitors of intracellular signal transduction pathways such as the Janus kinase (JAK)/signal transducer and activation of T cells (STAT) that transduce cytokine signals from the cell surface receptor to the nucleus (inhibitors of JAK-1, 2 and 3);

- the inhibition of adhesion of inflammatory cells to endothelium of inflamed tissues, using, for example, an anti-integrin monoclonal antibody (eg, natalizumab or efalizumab);
- the promotion of a regulatory mechanism, such as apoptosis, and, in particular, enhancement of peripheral regulation by the regulatory T cells (eg, anti-CD3 immunotherapy, or IL-2 therapy are currently being analysed in systemic lupus erythematosus and cryoglobulinaemic vasculitis).

In conclusion, it is tempting to speculate that as the cellular and molecular basis of immune mediated diseases become better defined, these clinical disease entities may be reclassified according to the specific pathological pathways involved, as opposed to the patterns of clinical signs and symptoms. This is likely to facilitate diagnosis and the identification of better targeted therapies.

Summary points

- The immune system is a sophisticated machine consisting of a first-line defence barrier called the innate immune system and an acquired arm, termed the adaptive immune system, capable of requiring a memory for specific antigens.
- The innate immune system relies on soluble mediators (eg, complement proteins) and cells (macrophages, dendritic cells, polymorphonuclear cells, mast cells). The latter have the capacity of phagocytosing pathogens and produce inflammatory mediators rapidly. This phase comprises inflammatory mediators (enzymes, antimicrobial peptides, free radicals) as well as vasoactive and chemotactic factors required to facilitate the influx of immune cells.
- The activation of innate immune cells occurs mainly through recognition of microbial products called PAMPs, by receptors called PRRs, among which TLRs and NOD-like receptors. PAMPs induce cellular activation, production of acute inflammatory mediators (enzymes, prostaglandins, nitric oxide) and upregulate molecules on the surface of antigen-presenting cells that activate the adaptive immune system.
- Innate immune cells are programmed to induce an immediate response to the pathogen, whereas the adaptive immune cells (lymphocytes) require training that occurs in the central lymphoid organs (thymus and bone marrow), followed by activation in the peripheral lymphoid organs (spleen, ganglions, bone marrow, mucous membranes).
- Maturation of T cells (in the thymus) and B cells (in the bone marrow) is a fundamental step designed to select 'good' lymphocytes that are highly efficient in destroying pathogens, but incapable of reacting against self-tissue/host proteins. Therefore, these lymphocytes must be tolerant; otherwise, an autoimmune disease will occur.
- The activation of T and B cells in the peripheral lymphoid organs occurs when in contact with the antigen presenting cells of the innate immune system, the 'job' of which is to trap the pathogens in the peripheral tissues in order to present these to lymphocytes. The major antigen presenting cell for T cells is the dendritic cell; the most important intermediate to couple the innate and adaptive immune systems. This antigenic activation occurs mainly in the lymph node, but also in the spleen as well as in cutaneous tissues and mucous membranes.
- 'Professional' antigen presenting cells, such as dendritic cells and macrophages, are a major link between the innate and adaptive immune systems. They play a fundamental role in the induction of immune responses to pathogens as well as the prevention of immune responses to host tissues.
- Humoral immunity plays an important role in the extracellular adaptive immune response. It is characterised by the production of antigen-specific antibodies (immunoglobulins) by antibody-secreting B cells, also called plasma cells. B cells recognise (unprocessed) antigens by means of their BCR. Antibodies are able to bind antigen in order to neutralise or opsonise antigens for lysis by complement or cellular responses.
- Intracellular immune mechanisms are orchestrated through T cells and NK cells. T cells recognise (processed) antigens in the context of HLA, by means of their TCR. HLA molecules, present on the surface of cells, display a molecular fraction of a protein, called a peptide.

- Prevention of an unwanted immune response against self-proteins by T cells occurs through a central tolerance mechanism, initiated during T cell development in the thymus as well as peripheral control systems, including regulatory T cell populations.
- Pro-inflammatory (IL-1, IL-6, TNF α , IL-17) and anti-inflammatory (IL-10, TGF β) cytokines and chemokines provide molecular signals for communication between cells, and play significant roles in sustaining and regulating inflammatory reactions.
- Anomalies of the immune system may arise through functional defects (immune deficiencies and deranged homeostasis) or through excessive functioning (autoimmune diseases, auto-inflammatory syndromes and allergies).
- Listed among the immune deficiencies are congenital diseases (Mendelian inheritance), which can be distinguished from those that can be acquired (most important: HIV infection or immunosuppressive treatment).
- Loss of homeostatic equilibrium in the immune system linked to gene mutations can be manifested as lymphoproliferative and autoimmune diseases, such as the ALPS syndrome that is linked to mutations in the Fas/Fas ligand system.
- Auto-inflammatory diseases are often characterised by genetically acquired deregulation of inflammation. Periodic fever syndromes can be defined among these and comprise the familial Mediterranean fever, hyper-IgD syndrome and other diseases linked to anomalies of the NOD-like receptor genes, such as certain forms of Crohn's disease and Blau's syndrome.
- Autoimmune diseases are mostly characterised by aberrant immune responses of the adaptive system against self-molecules and are often associated with the presence of certain HLA molecules and specific auto-antibodies.

IN-DEPTH DISCUSSION I

NOD-Like receptors as innate sensors involved in auto-inflammatory disorders.

Auto-inflammatory diseases are caused by the activation of the innate immune system. These disorders are often characterized by intense episodes of inflammation leading to symptoms like fever, rash and swelling of the joints. Auto-inflammatory disorders are not associated with the HLA-system and no auto-antibodies are present.

Many auto-inflammatory disorders are caused by mutations in proteins that are intimately involved in the activation of immune cells through the release of pro-inflammatory molecules. These proteins belong to the NOD-like receptor (NLR)-family and have in common that they, once activated, can proteolytically process several protein substrates including pro-interleukin-1 into their biologically active forms through a caspase-1-mediated process. NOD-like receptors, or NLRs, play a prominent role in the innate immune defence against pathogens, but are also involved in normal tissue homeostasis. Prominent members of the NLR-family are the NOD-2 (nucleotide-binding oligomerization domain) proteins, as well as inflammasomes.

The investigation into the biology of these proteins has been intense in the last years as they are linked to several inherited auto inflammatory syndromes, but are also playing a role in diseases like inflammatory bowel disease (IBD). For example, one of the most prominent genetic risk factors for IBD is found in NOD2, where mutations in the gene that encodes NOD2 predisposes to IBD. NOD2 has an important role in innate immunity as sensor of microbial components derived from bacterial peptidoglycan such as muramyl dipeptide. Apparently, when mutated, it can give rise to aberrant immune response to (gut) bacteria leading to a predisposition for IBD.

NLR-family members have as common feature that they are expressed in the cytosol and when activated through direct- or indirect recognition of a “danger-associated signal” can quickly activate downstream signalling pathways such as those dependent on NF- κ B, or the caspase-1 triggered cleavage of pro-IL-1, pro-IL-18 or pro-IL-33. The latter will lead to the quick activation and release of IL-1 and thereby to immediate inflammation.

Several mutations in NLR-family members, which together consists of 22 proteins, are intimately associated with monogenic and autosomal dominant inflammatory disorders that are characterized by an excessive production of IL-1. For example, mutations in NLRP3 are strongly associated with rare, monogenic and autosomal inflammatory diseases such as neonatal-onset multisystem inflammatory disease (NOMID), familial cold auto inflammatory syndrome (FCAS), Muckle–Wells syndrome and cryopyrin-associated periodic syndrome (CAPS). Similarly, mutation in NOD-2 are not only associated with IBD, but also Blau syndrome, whereas other mutations located in other NLR-family members are associated with familial psoriasis (PSORS2) or CARD14-mediated pustular psoriasis (CAMP5) (please see also figure below for overall structure of NLRs).

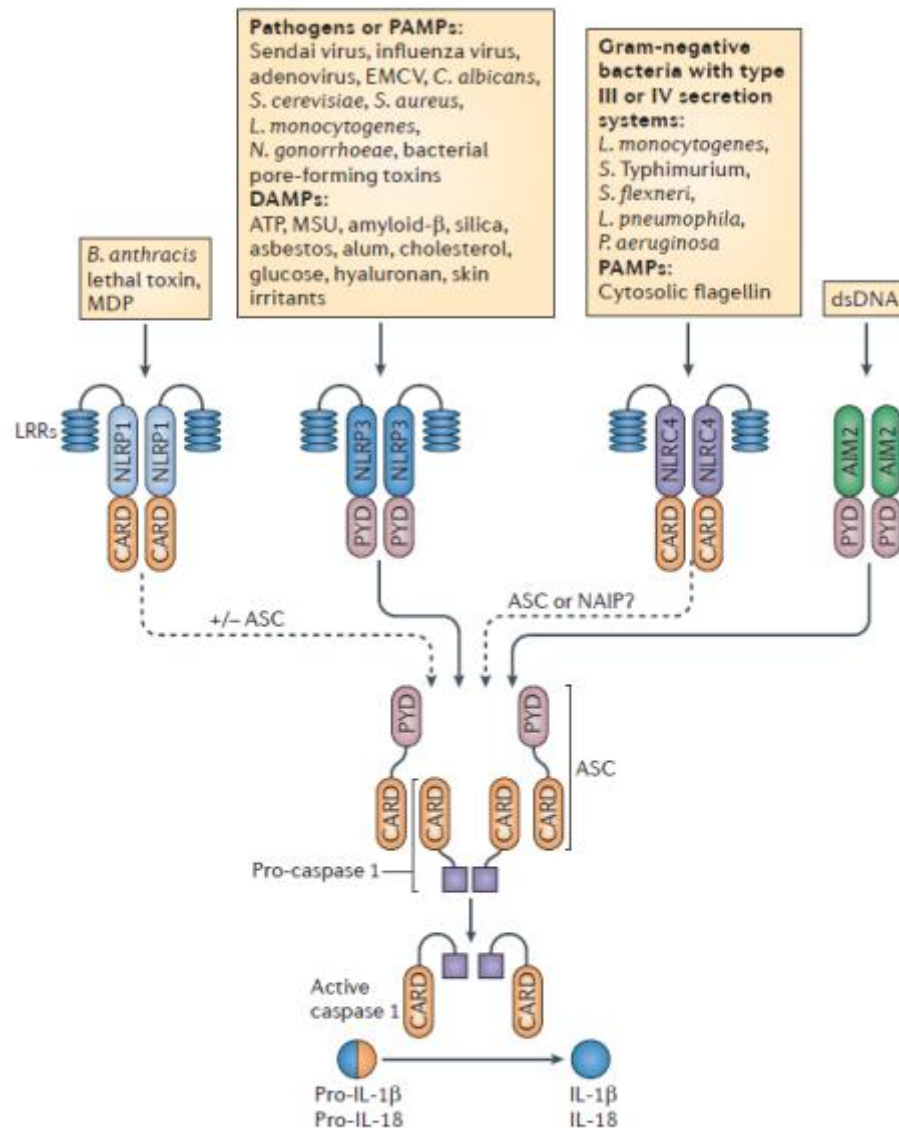

Figure 3 | The NLRP1, NLRP3, NLRC4 and AIM2 inflammasomes. The NOD-, LRR- and pyrin domain-containing 1 (NLRP1) inflammasome is activated by *Bacillus anthracis* lethal toxin and muramyl dipeptide (MDP). The NLRP3 inflammasome is activated by exposure to whole pathogens, pathogen-associated molecular patterns (PAMPs), damage-associated molecular patterns (DAMPs) and environmental irritants. The NOD-, LRR- and CARD-containing 4 (NLRC4; also known as IPAF) inflammasome is activated by Gram-negative bacteria with type III or IV secretion systems, and the absent in melanoma 2 (AIM2) inflammasome senses double-stranded DNA (dsDNA). Other complexes (not shown) — such as NLRP6-containing complexes that regulate interleukin-18 (IL-18) production — also exist²⁴, and pyrin probably regulates an inflammasome complex containing ASC but not NLRP3 that activates IL-1 β processing⁶⁹. CARD, caspase recruitment domain; EMCV, encephalomyocarditis virus; LRR, leucine-rich repeat; MSU, monosodium urate; PYD, pyrin domain.

Obviously, not all auto-inflammatory disorders are caused by genetic defects such as exemplified by gout. Gout is a disease characterized, like many inherited inflammatory disorders, by recurrent attacks of acute inflammation, in this case caused by crystals deposit in joints, tendons and surrounding tissues. However, like

the inherited inflammatory disorders, also the deposition of crystals lead ultimately to the activation of the NLR-family, and hence the acute and rapid activation of the IL-1 pathway, subsequently followed by the signs and symptoms characteristic for gout.

Together, recent research into the basic activation of the innate immune system has revealed the relevance and importance of NLRs in the recognition of microbial ligands and danger-signals leading to the production of IL-1- and IL-1-related cytokines. NLR-family triggering can, therefore, lead to an acute inflammatory reaction leading to the control of infection. However, when going uncontrolled, either by genetic aberrations or response to the innocent triggers, they can also be at the basis of several auto-inflammatory disorders such as gout, CAPS or NOMID.

IN-DEPTH DISCUSSION II

Autoantibodies in Rheumatoid Arthritis

1. Rheumatoid Factors

1.1 Introduction

Rheumatoid factors (RF) are antibodies that are usually directed against the Fc portion of the immunoglobulin G (IgG) molecule (antibodies to the Fab portion have also been described, but their clinical significance is unclear). Although RF may be of any immunoglobulin class, it is the RF of IgM class that are measured in diagnostic laboratories. IgG rheumatoid factors have been associated with vasculitis, but have not, so far, found a useful role in diagnosis and management in routine clinical practice. On the other hand, IgA RFs have in the past been considered to be more closely associated with cartilage loss and bone erosion in RA. First documented 60 years ago, IgM RF still remains the commonest assay used for the diagnosis of RA (and the sole serological parameter included in the 1987 American College of Rheumatology RA classification criteria for rheumatoid arthritis). Although IgM RF has a sensitivity of ~70%, it has a relatively low specificity as it may be detected in other rheumatic diseases, acute and chronic infections, and at low titre in the elderly healthy population [1]. Indeed, IgM rheumatoid factor is not specific for RA, being found at high titres in Sjögren's syndrome, in a subset of patients with cryoglobulinaemia and in ANCA-associated vasculitis, among others. Lower levels may also be found in SLE, systemic sclerosis, polymyositis and in patients with infections. The RF detected in diseases other than RA is indistinguishable from that detected in RA. The diagnostic specificity of IgM rheumatoid factor is therefore quite low, and, when the appropriate healthy and disease control groups are taken into account, may only be around 50%.

From the work of Schlomchik's group (Leadbetter et al Nature 2002), we know that our IgG become immunogenic when they are part of immune complexes (IC). It is the consequence of the presence of a second signal given by PAMPS present in the antigenic part of the IC to PRR of quiescent B cells with an anti-Fc activity. This explains that RF may appear in all situations when there is an excess of IC: chronic viral infection like HCV infection, acute infections like endocarditis and all the systemic autoimmune diseases.

1.2 Clinical Significance

The commonest finding in RA is the detection of IgM RF, but as described above this finding is not restricted to RA. The finding of both IgM and IgA RF has a higher specificity for RA [2], but is also found in ~25% of patients with primary Sjögren's syndrome. In the context of RA, IgM and IgA RF seem to be indicative of a more severe form of the disease and it has been proposed that these specificities, together with anti-CCP, are useful prognostic markers of RA [3]. However, there is no close correlation between the levels of IgM and IgA RF and markers of disease activity such as ESR and CRP [4]. There has been a report documenting high IgA RF titres associated with inadequate clinical responses to TNF blockade [5], but this association requires confirmation, and as yet no clear mechanism is apparent for such a correlation. The levels of IgM rheumatoid factor may fall

following treatment with TNF-blocking agents or with anti-B cell therapy, although there remains no clear relationship between these changes in titre and clinical response to drug.

1.3 Methodology

RFs may be measured by particle agglutination, nephelometry, turbidometry or by ELISA, and methodological variation may lead to conflicting results being obtained when two different technologies are used in parallel. Most of these techniques have been clinically validated but it is important to interpret the results of any assay in conjunction with the levels found in a normal population as well as in disease profiles relevant for the technology used. It is also important to ascertain whether the assay detects specific RF isotypes, as opposed to RF activity (i.e. IgG binding activity). The commonest methodology has traditionally been passive agglutination of IgG coated beads. However, in recent years these techniques have increasingly been replaced by the use of immunochemical techniques on high throughput analytical platforms.

2. Antibodies to Citrullinated Protein Antigens (ACPA)

2.1 Introduction

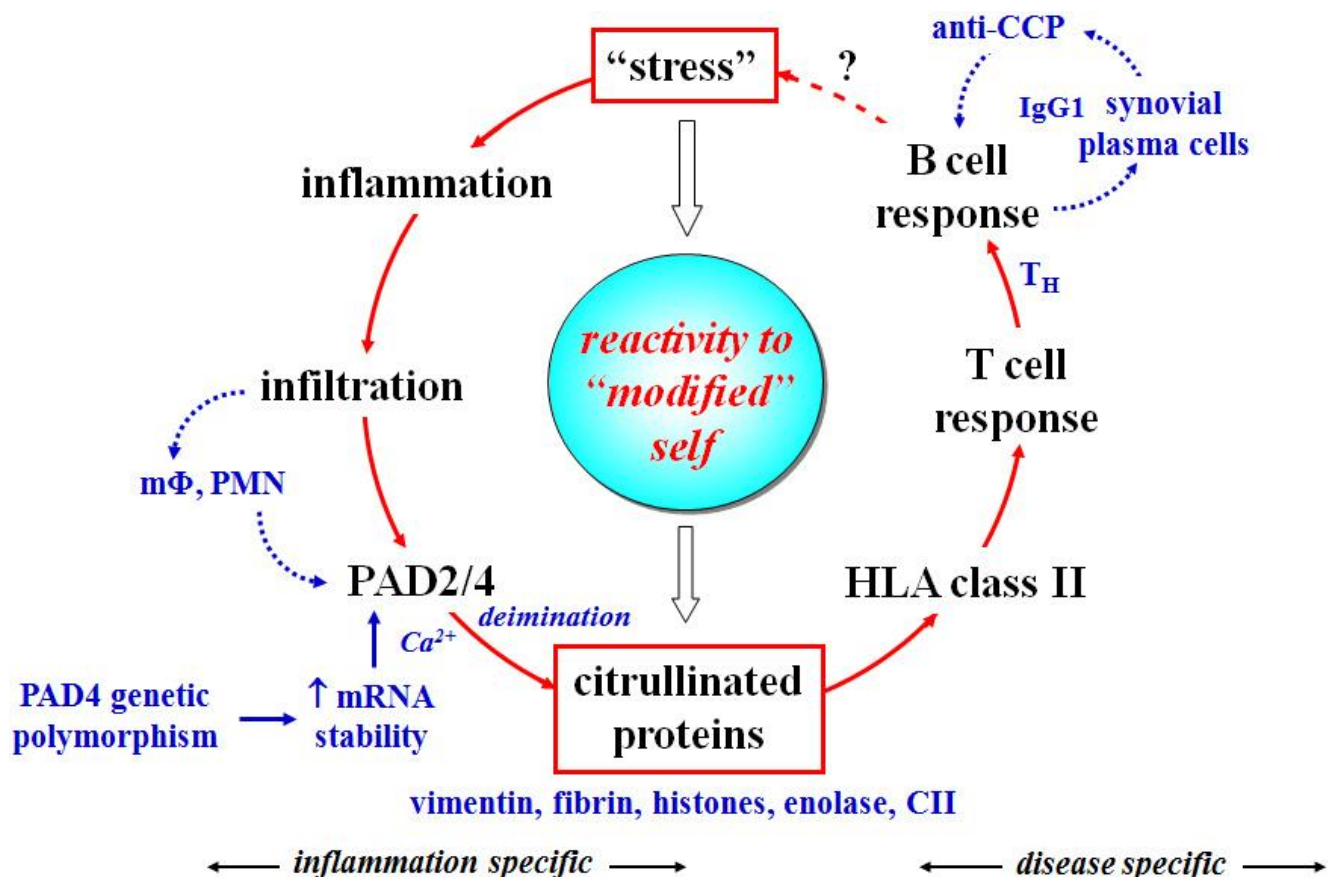

Over the last decade there has been an explosion of interest in research into antibodies to citrullinated protein/peptide antigens (ACPA; reviewed in ref 6). Initially, the fine specificity of ACPA, besides the original study of anti-filagrin antibodies first described in 1998, was poorly defined. Today many ACPA specificities have been documented, perhaps the best documented being antibodies to citrullinated (or de-aminated) filagrin, fibrinogen, vimentin, type II collagen and alpha-enolase. The first commercially available anti-cyclic citrullinated peptide (CCP) antibody assay was launched on the market in 2001.

The history of ACPA is of interest. Anti-perinuclear factor antibody (APF) was first described in 1964, detecting granules around the nucleus of differentiating buccal mucosal epithelial cells by indirect immunofluorescence. However, this cellular source of antigenic substrate was only reliable in ~5% of donors and so the assay was not used routinely in clinical laboratory practice. The APF antibody had a sensitivity of 55-70% and a specificity of ~95% for RA. In 1979 [7], anti-keratin antibody (AKA) was noted by its staining of the epithelial cells of rat oesophagus stratum corneum; these autoantibodies had a sensitivity of 40-60% and a specificity of 90-99% for RA. In 1993, the antigen was identified as filagrin [8]. The molecular basis for the strong correlation between AKA and APF antibody positivity became clearer in 1995, when it was discovered that these autoantibodies recognised the same antigen, namely filagrin [9]. However, technical problems associated with the protein used in the anti-filagrin antibody (AFA) assay, which only had ~ 50% sensitivity for RA, again prohibited routine use in the clinical setting. It was subsequently determined that AFA actually targeted not native amino acid epitopes but citrullinated residues on the filaggrin polypeptide [10]. Antibodies to the citrullinated (or deiminated) alpha and beta chains of fibrin have also been documented as markers of RA. Thus, in early RA,

the autoantibody has a sensitivity of 56-61% (rising to ~70% in late RA), a specificity of 93-99%, PPV ~94%, and may also be detected in a subset (~ 10-15%) of seronegative (i.e. RFneg) patients [11].

Citrulline is not a naturally occurring amino acid. Thus, citrullination (deimination) arises through post-translational protein modification through the conversion of a positively charged arginine amino acid residue into a neutrally charged citrulline. When arginine is oxidised, a terminal nitrogen of the arginine side chain is replaced by an oxygen molecule, with the reaction using one water molecule and releasing ammonia (NH₃) as a by-product. This process is catalysed by a family of calcium-dependent enzymes called peptidylarginine deiminases (PADs), with certain subtypes of PADs being expressed in monocytes (PAD4) and macrophages (PAD4 and PAD2) [12], cells playing a key role in the pathogenesis of RA and whose synovial numbers correlate with rheumatoid joint inflammation [13]. A thought provoking hypothesis for the role of cell death, PAD enzymes and anti-CCP antibodies in RA has been proposed by Zendmen et al [14]. A schematic of citrullination in the context of inflammation is illustrated in Figure 1.

Figure 1 - immune response to CPA is more disease specific

Recent studies have shown that the anti-CCP response in RA is made up of a number of antibodies which react with different citrullinated peptides. These include antibodies to citrullinated forms of filaggrin, fibrinogen, fibronectin, vimentin, type II collagen and alpha-enolase. The repertoire of reactive specificities is

heterogeneous and varies from patient to patient [15]; extensive profiling has not identified to date any correlation between the repertoire of APCA and either clinical phenotype or outcome. Antibodies to citrullinated vimentin and to citrullinated alpha enolase have been shown to be very tightly linked to the genetic-environmental complex of shared epitope, PTPN22 and smoking which is known to be a significant risk factor for the development of RA [16]. Despite this finding there has been little association found between the presence of a specific antibody subtype and disease features such as erosions. As has been reported with anti-CCP antibodies, these specific ACPA can be detected years before the clinical onset of the disease, and one study has shown that maturation of the ACPA repertoire, in terms of both antigenic specificity and immunoglobulin isotype usage, occurs predominantly before the onset of clinical disease [17].

2.2 Clinical Significance

The most commonly used anti-CCP antibody (termed anti-CCP2) assay exploits a mixture of synthetically derived cyclic citrullinated peptides with no known homology to tissue proteins, and was generated with RA sera after screening large libraries of derivatised peptides. As such, CCP2 is not an antigen in the conventional sense of the term, but the benefit of synthetic peptide production and purification is that it is cheap and reproducible, with uniform citrullination of the peptides.

The anti-CCP2 assay has been reported to have a sensitivity as high as 80% and a specificity of 95-99%. Its production is independent of RF and so there exist subsets of anti-CCP positive patients (~ 10-15%) who are negative for IgM RF. Interestingly, the association between HLA-DRB1 and patients with RA appears to be intimately linked with anti-CCP, independently of RF, suggesting that SE+ HLA-DRB1 alleles predispose not to RA per se, but to immunity to citrullinated proteins [18]. While IgM RF levels have been found to decrease with treatment, anti-CCP antibody concentrations do not appear to change significantly, limiting the use of anti-CCP as a marker of disease activity or as an indicator of response to treatment. There is also no correlation between the levels of anti-CCP and markers of disease activity such as ESR and CRP [4]. There is increasing evidence that anti-CCP antibodies are also detected at a low frequency in patients with other connective tissue diseases including Sjögren's syndrome, systemic lupus erythematosus, systemic sclerosis, mixed connective tissue disease and idiopathic inflammatory myositis. A common clinical denominator, which could account for these findings, may be the presence of joint erosions in patients that have these other conditions, since anti-CCP positive RA has been associated with a more aggressive disease course, with respect to radiographic progression [19]. In a cross-sectional study of patients enrolled in the British Society of Rheumatology Biologics Register, the presence of anti-CCP antibodies was associated with a poorer response to anti-TNF agents at 6 months [20]. However, a model comprising both clinical and serological predictors could only account for a small proportion of variance in drug response ($R^2=0.17$) and would be of no value in predicting an individual patient's outcome. Recently, a novel subtype of antibodies that recognise homocitrulline have been identified [21]. These arise through carbamylation of self-proteins and are termed anti-CarP

autoantibodies. They appear to be specific for RA, distinct from anti-CCP (since they do not cross react) and can be found in a proportion of RA patients who are negative by anti-CCP2 testing. The full clinical utility of this subset await further investigation. Autoantibodies to PAD have also been described.

2.3 Methodology

Assays detecting antibodies to citrullinated peptides or proteins use conventional ELISA methodology. It has also become common research laboratory practice to screen for the presence of citrullinated specificities by de-aminating recombinant antigens in vitro, and comparing the reactivity of RA serum to both unmodified and modified antigen by Immunoblotting or ELISA. A number of the commercially produced assays use a range of different antigenic targets from varying sources, and this has led to some variations in specificities and sensitivities from those recorded with the prototype anti-CCP2 test. Somewhat confusingly, some of these newer generation assays are also referred to as 'CCP'.

3. Future Developments

The advent of ACPA has defined a new era in understanding autoimmunity in RA. Whether they reflect autoimmunity to “inflammation”, or arise as a consequence of cell stress and death remain topics of much debate [22]. Following these discoveries, and influenced by the recognition of the heterogeneous nature of the disease and the advent of costly biological therapy, much time and energy is currently being invested in the finer classification of the autoantibody response in RA as a potential method of sub-classifying RA patients. It may be that, among other immunological parameters, ACPA profiles will turn out to be most helpful in identifying those subjects with joint pains (arthralgia) at most risk of developing RA. For example, in blood bank serum samples, one study showed that 34% of the RA patients were positive for ACPA up to nine years prior to diagnosis (23). Whilst another study showed that 49% of the RA patients tested positive for IgM- RF and/or ACPA at a median of 4.5 years before symptom onset (24). Using banked sera from the Nurses' Health Study, anti-CCP antibodies were detected up to 12 years prior to diagnosis (25). ACPA may also inform outcome, disease severity, as well as response to therapy. In addition to IgM, IgA RF and anti-CCP it is likely that other autoantibody markers will emerge in the coming years. It will prove be challenging for both the clinician and the pathology laboratory to provide robust, clinically informative assays. It would seem likely that one productive way forward will be to use multi-parametric assay systems where a panel of the dominant specificities are measured in a single assay, perhaps combined with an algorithm which enables the clinician to interpret the results obtained with respect to the sub-classification of disease, the clinical phenotype and longer term outcome for that disease subset.

Spondyloarthritis: Pathogenesis, clinical aspects and diagnosis

Stefan Siebert, George Fragoulis, Iain McInnes

A previous version was coauthored by Uta Kiltz, Xenofon Baraliakos, Cecilia Mercieca, Andrew A Borg, Maxime Dougados and Robert Landewé

LEARNING OUTCOMES

- ➔ Discuss the concept of spondyloarthritis (SpA)
- ➔ Describe the pathophysiology of these disorders and the role of genetic and environmental factors
- ➔ Explain the different hypotheses for the role of HLA-B27 in the pathogenesis of these disorders
- ➔ Explain the approach to the diagnosis of SpA
- ➔ Improve assessment of patients with SpA, especially disease 'activity', 'severity' and 'refractory' characteristics of the disease
- ➔ Present treatment strategies for patients with ankylosing spondylitis
- ➔ Describe the use of the different tools allowing better patient monitoring

1 The concept of spondyloarthritis

Spondyloarthritis (SpA) is a heterogeneous group of chronic inter-related inflammatory arthropathies affecting mainly the spine but also showing peripheral symptoms in the joints, entheses and certain extra-articular sites. The SpA group includes axial SpA (axSpA ; incorporating non-radiographic axSpA and ankylosing spondylitis (AS)), peripheral SpA, reactive arthritis (ReA), psoriatic arthritis (PsA), enteropathic-related arthritis and juvenile SpA (box 1). AS is termed the prototype of SpA. The introduction of the new ASAS classification criteria for axSpA and peripheral SpA has facilitated understanding of the concept of SpA and incorporated this into clinical practice and trials.

Box 1 Clinical presentation of SpA

Disease subgroups

- AxSpA including AS and non-radiographic axSpA
- Peripheral SpA
- PsA
- Reactive arthritis
- Inflammatory bowel disease/enteropathic-related arthritis
- Juvenile SpA

Clinical features

- Rheumatological manifestations
 - o Axial involvement
 - o Peripheral arthritis
 - o Enthesopathy
- Extra-articular features
 - Acute anterior uveitis
 - o Psoriasis
 - o Inflammatory bowel disease
 - o Cardiac involvement (e.g., heart block, aortic insufficiency)
- Genetic background
 - o Family history
 - o HLA-B27 antigen

AS, ankylosing spondylitis; axSpA, axial spondyloarthritis ; PsA, psoriatic arthritis; SpA, spondyloarthritis.

Adapted from Dougados and Hochberg, Best Pract Res Clin Rheumatol 2002;16:495–505.

SpA occurs primarily in genetically predisposed individuals, particularly those who are positive for the major histocompatibility complex (MHC) class I molecule HLA-B27. However, additional genetic and environmental factors play a role in its pathogenesis. It can be difficult to differentiate these disorders because their clinical features may overlap, which is why undifferentiated forms of SpA are also recognised.

The monitoring and treatment of these diseases is related more closely to the clinical presentation (axial versus peripheral) than to the precise diagnosis. The rheumatic manifestations include inflammation of the spine and sacroiliac (SI) joints, peripheral arthritis and enthesitis (inflammation at the entheses, the sites of attachment of tendons, ligaments, fasciae or joint capsules to bone). Enthesitis is the distinguishing pathological feature of SpA. The extra-articular manifestations of the disease may be similar whatever the SpA subgroup or may be specific to a SpA subgroup, such as skin lesions in PsA, gut involvement in inflammatory bowel disease-related arthritis and the oculo-urethro-synovial triad in classic ReA.

1.1 Subtypes

SpA can present with a wide spectrum of clinical features. Certain features occur more commonly in some subtypes of SpA. Table 1 shows typical patterns of SpA subtypes. However, symptoms overlap and so it is possible for any of the principal clinical features to be present in any of the distinct diseases.

Table 1 Prevalence of clinical features/disease in spondyloarthritis (SpA)

Clinical features/diseases	AxSpA	Psoriatic arthritis	Enteropathic arthritis	Reactive arthritis	Juvenile-onset SpA	Peripheral SpA
Axial involvement	+++	++	+	+	+	+
Peripheral arthritis	+	+++	++	++	++	+++
Enthesitis	+	++	+	+	+	++
Extra-articular features:						
Uveitis	++		+	+	+	+
Psoriasis		+++				+
Diarrhoea	+		+++	+		+
Conjunctivitis, urethritis				+++		
Aortic insufficiency	+		+	+	+	+

1.1.1 AxSpA including AS

AS is the prototype of axSpA. It is characterised by the presence of spinal pain, resulting in limitation of spinal mobility and radiological evidence of structural changes in the SI joints and the spine. Nevertheless, other manifestations can also be seen, such as enthesitis (40–60%), acute anterior uveitis (30–50%) and colitis (15% symptomatic, 60% microscopic). The disease course of axSpA is highly variable and characterised by ongoing axial inflammation and radiographic progression associated with restricted mobility of the spine and decreased function. Since axSpA usually starts in early adulthood, the lifetime impact of the disease can be considerable, resulting in stiffness, fatigue, limitation of social activities and participation.

The modified New York criteria (see box 7, section 6.1 Plain radiographs) have been widely accepted in clinical practice and in clinical trials to classify patients as having AS. Although they work well in established disease,

they require evidence of structural radiographic changes, so are limited for capturing the early disease stages and not all patients with suggestive clinical features develop radiographic changes. This was the reason why the Assessment of SpA international Society (ASAS) developed new classification criteria for patients with axSpA (with and without radiographic changes) and also for those with peripheral SpA (for further details see boxes 8 and 9, section 7. Classification).

1.1.2 Psoriatic arthritis

Psoriasis is a common skin disease among Caucasian subjects (1–3% prevalence), but uncommon in some other ethnic groups, such as Afro-Caribbean and Native American populations (0–0.3%). It affects men and women equally. About 10–20% of patients have associated PsA. Psoriasis usually predates the appearance of arthritis, but the onset is simultaneous in 20% of patients, and in up to 15% the arthritis may precede the onset or diagnostic recognition of psoriasis. The arthritis usually starts between 30 and 50 years of age, but may also begin in childhood. In most patients, exacerbations and remissions of skin and joint involvement occur with little or no apparent relationship. PsA is a heterogeneous disease that may involve the peripheral or axial skeleton. Recognisable PsA phenotypes include: asymmetric oligoarthritis; predominantly distal interphalangeal disease; peripheral polyarthritis (rheumatoid-like); predominantly enthesal disease; or dominant axial disease (~5%). Many patients also develop sausage-shaped swelling of digits called dactylitis. Occasionally patients present with a mutilating type of disease affecting mainly the digits with osteolysis, called ‘arthritis mutilans’. PsA is characterised radiologically by juxta-articular new bone formation and erosions (in contrast to rheumatoid arthritis which is not associated with new bone formation). Treatments were historically adapted from those used in rheumatoid arthritis, but increasingly new biologic therapies are adapted from psoriasis.

The CASPAR (Classification Criteria for Psoriatic ARthritis) criteria were developed by an international study group and have a sensitivity of 91% and a specificity of 99% (box 2).

Box 2 CASPAR (Classification Criteria for Psoriatic ARthritis)

A patient must have inflammatory articular disease (joint, spine or entheses) AND ≥3 points from the following:

- Current psoriasis (score 2) or a personal or family (1st or 2nd degree relative) history of psoriasis (score 1)
- Dactylitis—score 1
- Juxta-articular new-bone formation on x-ray—score 1
- Rheumatoid factor negativity—score 1
- Nail dystrophy—score 1

Adapted from Taylor et al, Arthritis Rheum 2006;54:2665–73.

The SAPHO (Synovitis, Acne, Pustulosis, Hyperostosis, Osteitis) syndrome also presents with skin and musculoskeletal features that suggest it may belong in the SpA spectrum.

It shares many clinical and radiological similarities with SpA and in particular with PsA, including lesions similar to pustular psoriasis (Figure 1), sacroiliitis and enthesopathy. Furthermore, the possible role of IL-17 in the pathophysiology of SAPHO has been recently appreciated, suggesting shared pathophysiology.

Figure 1: palmar pustulosis in a patient with SAPHO syndrome. [Source: CRI (Club Rhumatismes et Inflammation, <http://www.cri-net.com>)]

On the other hand, SAPHO does not exhibit a strong HLA-B27 association or familial predisposition and is not associated with uveitis or inflammatory bowel disease (IBD). The scarcity of the disease and lack of large-scale clinical studies have precluded the in-depth exploration of the disease and its optimal treatment.

Hidradenitis suppurativa is an inflammatory skin condition of hair follicles in areas of friction in the body (e.g. axilla, groin) that has also been reported to be associated with IBD and SpA. Hidradenitis suppurativa is also strongly associated with obesity and the metabolic syndrome. Interestingly, the arthritis seen in association with hidradenitis suppurativa is HLA-B27 negative and may often flare up in conjunction with flares of the skin disease.

1.1.3 Enteropathic arthritis

Enteropathic arthritis describes the occurrence of inflammatory arthritis in patients with ulcerative colitis or Crohn's disease. The prevalence of arthritis in IBD ranges from 17% to 20%, with a higher prevalence in Crohn's disease.

The most common manifestation of enteropathic arthritis is inflammation of the knee and ankle joints as part of a peripheral oligoarthritis. The peripheral arthritis may be transient, migratory and non-deforming, although in some cases the arthritis may become chronic and destructive. Axial involvement and enthesitis may also be found, often as incidental findings on imaging such as abdominal CT scans. Intestinal symptoms usually antedate or coincide with joint manifestations, but arthritis may precede the intestinal symptoms by years.

1.1.4 Reactive arthritis

ReA describes an episode of aseptic peripheral arthritis that occurs within 1 month of a primary infection elsewhere in the body, usually a genitourinary infection with *Chlamydia trachomatis* or enteritis due to Gram-negative enterobacteria such as *Shigella*, *Salmonella*, *Yersinia* or *Campylobacter* species. Genitourinary tract infection with *Chlamydia trachomatis* is the most commonly recognised initiator of ReA in developed countries, whereas infections with enterobacteria are the most common triggers in developing parts of the world (box 3). In about 25% of cases, however, the triggering organism is unknown.

Box 3 Bacteria that trigger reactive arthritis

- *Chlamydia trachomatis*
- *Shigella flexneri*
- *Salmonella* spp
- *Yersinia enterocolitica*
- *Yersinia pseudotuberculosis*
- *Campylobacter fetus jejuni*
- *Clostridium difficile*
- Intravesical injection of bacilli Calmette–Guérin (BCG) to treat bladder cancer
- *Chlamydia pneumoniae* (unconfirmed)

Adapted from Smith et al, Best Pract Res Clin Rheumatol 2006;20:571–92.

ReA is typically an acute, asymmetrical oligoarthritis and is often associated with one or more characteristic extra-articular features, such as ocular inflammation (conjunctivitis or acute iritis), enthesitis, mucocutaneous lesions, urethritis and, on rare occasions, carditis. Conjunctivitis occurs in one-third of patients, usually at the same time as arthritis flares, and acute anterior uveitis may occur at some time in about 5% of patients. The triad of arthritis, conjunctivitis and urethritis is called classic ReA. However, most patients with ReA do not present with this triad. The average duration of arthritis is 4–5 months, but two-thirds of patients have mild musculoskeletal symptoms that persist for more than 1 year. Recurrent attacks are more common in patients with chlamydia-induced ReA. About 15–30% of patients develop chronic or recurrent peripheral arthritis, sacroiliitis or spondylitis. Most patients with chronic ReA have a positive family history of SpA or are HLA-B27 positive.

1.1.5 Juvenile-onset SpA

Juvenile-onset SpA usually manifests initially as peripheral arthritis or enthesitis in children aged 8–12 years, but onset at younger or older ages has been reported. There is a striking predominance of male subjects, particularly in the prepubertal stage. Juvenile-onset SpA clinically resembles adult SpA. Nonetheless, there are a few differences. Oligoarthritis affecting the knee, ankle and/or mid-foot is the typical initial presentation, and dactylitis is commoner in children. Systemic manifestations such as fever and weight loss occur more often in children, and enthesitis is prominent early on in the disease course.

The disease pattern often changes throughout childhood, adolescence and adulthood (e.g., from monoarthritis to a more complex form of disease, comprising axial, peripheral and extra-articular manifestations).

There are undifferentiated and differentiated forms of juvenile-onset SpA, which can be classified according to the International Association for Rheumatology criteria in the enthesitis-related arthritis subgroup. The adult Amor and European Spondyloarthropathy Study Group criteria have been validated in children and may also be used. Prognosis seems to be less favourable in juvenile-onset SpA than in adults. Structural damage, particularly in the feet, hips and spine, may lead to long-term functional impairment. Nearly 60% of patients have moderate-to-severe limitations 10 years after disease onset. The probability of remission is only 17% after a disease duration of 5 years.

2 Epidemiology

There is a paucity of good epidemiological studies to define the true incidence and prevalence of AS, axSpA and SpA, with wide variation as a result of geographic, demographic and methodological factors. Furthermore, most of the published epidemiological studies pre-date the development of the ASAS criteria for axSpA, and therefore most of the data relates to AS rather than axSpA. The prevalence varies significantly among different ethnic populations, being higher in white and certain Native American subjects and lower in African American and Asian subjects. The estimated global prevalence of AS ranges between 0.01% and 0.2%, with estimates of around 0.3% in European populations. Estimates for the prevalence of the broader axSpA population range from 0.3% up to 1.4% in Caucasian populations. The prevalence of AS parallels that of the HLA-B27 gene. Eight per cent of the healthy white population is HLA-B27 positive, while 4% of the healthy African American population is HLA-B27 positive. Ninety-two per cent of the white AS population is HLA-B27 positive, while 50% of the African American AS population is HLA-B27 positive. Up to sixty per cent of patients with ReA, PsA and enteropathic spondylitis are HLA-B27 positive, while 25% of patients with undifferentiated SpA are HLA-B27 positive. The chance of developing AS if one is HLA-B27 positive is 1–5%, increasing to 15–20% for people with an affected first-degree relative.

AS is more common in male subjects, with the male: female ratio being 2:1 to 3:1. However, in recent cohort studies of axSpA, this ratio has been found to be more equally distributed between genders. The reasons why male patients seem to progress more frequently than female patients towards development of AS are still unclear. The mean age of diagnosis is 26 years, but it can present from late adolescence to 45 years of age. There is often significant delay in diagnosis, especially in HLA-B27-negative patients. A shorter time to diagnosis was observed in patients with inflammatory back pain (IBP) or a positive family history because clinical suspicion tended to be higher.

3 Pathogenesis

The exact aetiology of SpA is still unknown but is likely to be a complex interplay of genetic and environmental factors with the microbiome and/or biomechanical stress (Figure 2)

Figure 2: SpA pathogenesis at a glance. A complex interplay of genetic, environmental factors, biomechanics and microbiome. Genetic alterations (including HLA-B27) and changes in the intestinal microbiota (dysbiosis) may produce aberrant immune responses, including activation of IL-23/-17 axis. Synovitis and gastrointestinal inflammation have been associated with IL-17 and TNF. Mechanical stress has been proposed also to associate with enthesitis and new bone formation in animal models of SpA. The involvement of IL-23, IL-17 and IL-22 can help explain the combination of erosive and osteoproliferative musculoskeletal changes seen in SpA.

3.1 Genetics

The involvement of genetic factors in determining susceptibility to SpA has long been suspected owing to frequent familial clustering of cases. The first genetic factor identified was gene encoding the surface antigen HLA-B27. Further genetic studies have led to the discovery of other genes important in disease susceptibility, including various HLA-B27 subtypes as well as non-HLA-B27 MHC and non-MHC genes, although it is not clear how these cause the disease. Studies are still in the early phase but potentially might provide further insight into disease pathogenesis and translate into future diagnostic and prognostic tools.

3.1.1 Methodology of genetic studies

The genetic analysis of complex, multifactorial diseases such as SpA is difficult owing to numerous factors. The model underlying the inheritance of the disease is unknown, although several genes are likely to be involved, which may be different from patient to patient (genetic heterogeneity). Moreover, the molecular variants of a gene (alleles) associated with disease susceptibility may be present in healthy subjects, suggesting that exposure to specific environmental factors is probably required to cause the disease to develop (incomplete penetrance). Discovering genes through family-based or candidate gene methods has not been successful. Using high-throughput microarray-based single nucleotide polymorphism (SNP) genotyping techniques has made it easier to identify genes associated with SpA more rapidly.

3.1.2 Family and twin studies

Twin studies in AS have shown a monozygotic concordance rate of around 70%. The genetic risk determines the risk of developing the disease and also the age of onset, clinical disease severity and radiographic severity, although to date, no genes have been consistently identified that are associated with the ankylosis process. Family and modelling studies have indicated that heritability contributes more than 90% to the overall susceptibility of developing AS, with <50% of the genetic risk due to HLA-B27. First-degree relatives have a 5–16% risk of developing the disease, while only 1–5% of HLA-B27 individuals develop AS, suggesting that other genes and environmental factors are involved. HLA-B27-positive relatives of patients with AS have a risk of developing AS that is 5.6–16 times greater than in HLA-B27 individuals in the normal population.

3.1.3 HLA-B27 gene

In 1973, the association of HLA-B27 with the development of AS was reported by two separate groups. Nevertheless, despite extensive investigation, the precise role of HLA-B27 in the pathophysiology of the disease remains unknown.

Three major theories have been proposed to explain how HLA-B27 contributes to the pathophysiology of AS:

1. Arthritogenic peptide theory

This theory proposes that HLA-B27 presents self-peptide complexes, thereby eliciting an autoreactive inflammatory response. However, to date, no arthritogenic peptides have been identified and the HLA-B27 animal model of SpA has been shown to be dependent upon CD4+ (helper) and not CD8+ (cytotoxic) T cells.

2. Endoplasmic reticulum stress and unfolded protein response theory

This theory proposes that HLA-B27 chains misfold and remain in the endoplasmic reticulum for longer. This in turn is proposed to result in endoplasmic reticulum stress and precipitate the pro-inflammatory unfolded protein response in an attempt at homeostasis. Recent data have however raised doubt about endoplasmic reticulum stress and the unfolded protein response model in AS.

3. Homodimerisation theory

HLA-B27 heavy chains have a propensity to self-associate and homodimerize, resulting in the expression of homodimers on the cell surface which are recognized by receptors on Th17 and natural killer cells, resulting in IL-17 production.

It should be noted that there are over 50 subtypes of HLA-B27 and that not all subtypes are associated with AS, while some even appear to be protective.

3.1.4 Non-HLA-B27 MHC genes

The MHC consists of about 220 genes, many of which have immunoregulatory functions. Other non-HLA-B27 MHC genes have been implicated in AS, but in many cases these have been confounded by linkage to HLA-B27, lack of sufficient marker density or not been replicated in other cohorts.

3.1.5 Non-MHC genes

More recently, large genome-wide association studies have identified a number of non-MHC genes which are associated with AS. The first study was carried out by the Wellcome Trust Case Consortium and the Australo-Anglo-American Spondyloarthritis Consortium (TASC, 2010*) which identified disease associations with interleukin 23 receptor (IL-23R) and endoplasmic reticulum aminopeptidase 1 (ERAP1). IL-23R is also linked with IBD and PsA. This may partially explain the frequent coexistence of these diseases.

The second study carried out by TASC was a complete genome-wide association study, which confirmed the above and identified new associations with IL-1R2, ANTXR2 and gene deserts (regions of the genome lacking protein-encoding genes) at chromosomes 2p15 and 21q22. Strong evidence to support association with the disease has also been demonstrated for the TNFSF15 and TNFR1 genes and a region on chromosome 16q,

including the TRADD gene. The exact role of these genes in AS remains to be determined, but of interest, many implicate innate immunity, antigen-presentation and the IL-23/17 pathway. ERAP-1 is of particular interest as the related protein also involved in antigen-processing (as a molecular ruler) and the ERAP-1 association with AS is only seen in patients who are HLA-B27 positive, indicating a gene-gene interaction.

3.2 Infections

Abnormalities in gut microbiota are increasingly implicated in rheumatic diseases including AS. The B27-transgenic (Tg) rats develop a SpA-like disease when housed in a probiotic (non-germ free) environment, but not, when raised under entirely germ-free conditions. Interestingly, colonisation of the gastrointestinal tract with normal gut flora, in particular *Bacteroides* spp, is sufficient to trigger inflammation. The severity of the SpA-like disease developed by B27-Tg rats correlates with levels of HLA-B27 expression.

Several gastrointestinal or genitourinary pathogens have been strongly implicated as triggers of HLA-B27-associated ReA in humans, including *Campylobacter* spp, *Chlamydia* spp, *Salmonella* spp and *Shigella* spp (box 2). While DNA from these organisms has been found by polymerase chain reaction in synovial cell and fluid samples, this remains controversial but does point towards a potential link between gut infection and joint inflammation. Recent studies have reported altered gut microbiota signatures in patients with AS or PsA, compared to healthy individuals, suggesting a potential role for alterations in the microbiome in the pathogenesis of SpA.

3.3 Inflammation

The most common sites of inflammation in AS include the SI joints, entheses, vertebral bodies adjacent to intervertebral discs, peripheral joint synovium, gastrointestinal tract and the eye. As many of these lesions are poorly accessible, information on histopathology is limited. In early sacroiliitis, synovitis with myxoid-appearing bone marrow and subsequent formation of granulation tissue is seen. Destroyed bone is eventually replaced and endochondral ossification results in bony ankylosis. Histologically, there is infiltration of T cells (CD4+ and CD8+) and CD68+ macrophages, proliferation of fibroblasts, and neovascularisation as well as tumour necrosis factor blocker (TNF α) and transforming growth factor β mRNA overexpression.

Synovitis in SpA displays features of other types of inflammatory arthritis, such as increased vascularity and endothelial cell activation, with increased expression of adhesion molecules and chemotactic factors. Relevant differences with rheumatoid arthritis include a tendency towards greater vascularity, greater CD4+ T cell and CD20+ B cell infiltration and few lymphoid aggregates. A recent study in a TNF α overexpressing mouse model suggested that mesenchymal stromal cells are the main target activated by TNF α signalling. These mice spontaneously develop an inflammatory disease characterised by Crohn-like arthritis, sacroiliitis, peripheral arthritis and enteritis (Armaka et al, 2008).

TNF α , but also other proinflammatory cytokines, are directly connected with Dickkopf-1, which leads to an upregulation of Dickkopf-1, a key target gene of TNF and an inhibitor of osteoblast differentiation and activation. AS is associated with reduced levels of Dickkopf-1 and sclerostin which has been proposed to result in increased new bone formation, the hallmark radiographic sign of AS.

Enthesitis is a hallmark of SpA. Inflammatory lesions are characterised by soft tissue inflammation and bone marrow infiltration with CD8 and CD4 T cells, B cells, macrophages and osteoclasts. This is more common at peripheral sites subject to biomechanical stresses and rich in fibrocartilage containing type II collagen and aggrecan proteoglycan, such as at the insertion of the Achilles tendon into the calcaneum. In the early phase of enthesitis, CD68+ and macrophages (1 month to 1 year of disease) seem to predominate, while abundant lymphocytes tend to be found in established disease. Recent animal models (covered in section 3.3.1) have started to help explain the link between systemic IL-23 and enthesitis.

3.3.1 The Interleukin 23/Interleukin 17 (IL-23/-17) axis

The IL-23/-17 pathway appears to play a crucial role in the pathogenesis of SpA. IL-23 is thought to be the main regulator of the axis. It consists of the p19 and p40 subunits, sharing the latter with IL-12. IL-23 is mainly secreted by activated macrophages and dendritic cells, and acts through the IL-12R β 1 and IL-23R receptors, driving a Th17 response. Ligation of IL-23 to its receptor upregulates the transcription factor ROR γ t leading to the production of various chemokines and cytokines including TNF α , IL-21, IL-26 and most importantly in SpA, IL-17 and IL-22 (Figure 3).

There are 6 forms of IL-17 (IL-17 A-F) with IL-17A and IL-17F being the best characterised. Activated CD4⁺ T (Th17) cells were initially thought to be the primary cells for IL-17 production, but, it is now recognised that many other cell types, including subpopulations of natural killer cells (NKp46+), CD8+ NK (NKT) cells, $\gamma\delta$ T cells, KIRDL2+CD4+, innate lymphoid cells, Paneth cells and neutrophils, can also express and possibly produce significant amounts of IL-17 (Figure 3).

The IL-17 cytokines are able to act in a plethora of cells since their receptors are expressed by hematopoietic cells, epithelial cells, endothelial cells, fibroblasts, keratinocytes, osteoblasts and monocytes/macrophages. The triggering of IL-17 receptor can lead to the expression of various pro-inflammatory cytokines (IL-6, IL-8, TNF α and IL-1 β), metalloproteinases, chemokines (CXCL8, CXCL1, CXCL5, CXCL2 and CXCL10) and RANKL by osteoblasts (Figure 3).

Figure 3: IL-23/-17 axis. IL-23 drives IL-17 and IL-22 production, which act on a number of target cells to produce inflammatory cytokines, chemokines and other molecules which lead to the phenotype seen in SpA. DC: Dendritic cells, MΦ: Macrophages, NK: Natural Killers, KIR: killer immunoglobulin-like receptor

There is now substantial evidence indicating that IL-23, IL-17 and IL-22 are central players in the pathogenesis of SpA (Smith and Colbert, 2014). Firstly, genetic studies in AS patients have revealed nucleotide polymorphisms in genes that are directly (*IL-23R*) or indirectly (e.g. *STAT3*) involved in this pathway. Some of these SNPs have been also found to associate with Crohn's disease and psoriasis. Secondly, data from animal models suggest a prominent role of the IL-23/-17 axis in SpA, including enthesitis. A recent study has reported a novel class of IL-23R positive (IL-23⁺RORγt⁺CD4⁺CD8⁻) T cells in enthesal sites in a mouse model which develops enthesitis in response to overexpression of IL-23, suggesting that not only can mechanical stresses trigger inflammatory responses, but that systemic IL-23 can lead to inflammation at these sites ([Sherlock JP et al, 2012](#)). Thirdly, human in-vivo and in-vitro studies, have shown that IL-17 is increased in the serum and the synovial fluid of SpA patients. In line with these finding, IL-17 producing cells are also found to be increased in the peripheral blood of patients with SpA, compared to healthy individuals; however, there are some discordances between studies. Surprisingly, in non-radiographic AS, CD4⁺ T cells producing IL-17 have been reported to be decreased in patients' peripheral blood, reflecting the possible differences among the phenotypes of axSpA. There are reports of increased IL-17 expression at the tissue level IL-17 in SpA patients,

although there is some inconsistency in the cells reported to express IL-17 and these studies require further validation.

Finally, a close association between the HLA-B27 and IL-17/-23 axis has been described. In HLA-B27/human β 2-microglobulin-transgenic (B27-Tg) rats, which display skin disease, arthritis and colitis suggestive of the SpA phenotype, Th17 cells were found to be expanded in lymph nodes and with increased frequency of IL-17-producing cells reported in their joints. Furthermore, misfolding of HLA-B27 in the endoplasmic reticulum leads to the formation of dimers and oligomers. One theory of HLA-B27 pathogenesis in AS that has received significant attention recently suggests that HLA-B27 homodimers are able to directly trigger CD4⁺ and NK cells expressing KIRDL2⁺, leading to IL-17 production. The efficacy of agents that inhibit IL-17 in recent clinical trials is further support that this is an important pathway in SpA and suitable target for therapeutic intervention.

4 Clinical features

4.1 Rheumatological manifestations

4.1.1 Inflammatory back pain

IBP is the first clinical manifestation in 75% of patients with axSpA. Classically, the pain starts in the lumbar region or at the lumbosacral junction. It is typically a dull pain of insidious onset, becoming persistent after a few months. The pain worsens with inactivity and improves with exercise and non-steroidal anti-inflammatory drugs (NSAIDs). Morning stiffness is often prolonged (>30 min) and nocturnal pain may awaken patients from sleep. On imaging, sacroiliitis or spondylitis is the dominant finding. If there is progression to ankylosis over time, the inflammatory pain usually lessens but is replaced by relevant functional impairment. Symptoms may be mild with intermittent flares and remission. An acute onset of pain, worsening symptoms with activity and radicular pain are more suggestive of a mechanical or degenerative cause, but both pathologies may also occur in the same patient. Three different sets of IBP criteria with similar sensitivities and specificities have been proposed (boxes 4, 5 and 6).

Box 4 Calin inflammatory back pain criteria

At least four of the following:

- Insidious onset
- Onset before the age of 40 years
- At least 3 months' duration
- Morning stiffness \geq 30 min
- Improvement with exercise

If four of these five criteria are fulfilled, sensitivity is 95% and specificity is 85%.

Adapted from Calin et al, JAMA 1997;237:2613–4.

Box 5 Berlin inflammatory back pain criteria

These require a patient to be aged <50 years with chronic back pain (>3 months duration) and at least two of the following:

- Morning stiffness ≥ 30 min
- Improvement with exercise but not with rest
- Awakening because of back pain during the second part of the night
- Alternating buttock pain

If two of these four criteria are fulfilled, sensitivity is 70% and specificity is 81%. If three out of four criteria are fulfilled, sensitivity is 33% and specificity is 98%.

Adapted from Rudwaleit et al, Arthritis Rheum 2006;54:569–78.

Box 6 ASAS expert criteria for inflammatory back pain

These require a patient to have chronic back pain (>3 months duration) and at least four of the following:

- Improvement with exercise
- Pain at night
- Insidious onset
- Age at onset <40 years
- No improvement with rest

The criteria are fulfilled if at least four of these five parameters are present.

Adapted from Sieper et al, Ann Rheum Dis 2009b;68:784–8.

IBP is the one of the main symptoms in SpA, but its value in diagnosis/classification and screening in primary care has still not been validated. It is estimated that about 10-15% of patients presenting with chronic back pain have IBP but only about 5% will have SpA. The sensitivity and specificity of IBP criteria are directly related to the pre-test probability of the patient having the disease and the stringency of the IBP criteria used. This is important, since the prevalence of IBP is much higher in rheumatology practices (25–50%) than in the primary care setting (5-15%), where the IBP criteria are probably less useful. Another important observation is that not all patients with axSpA have IBP. These observations have led to the removal of IBP as the first entry criterion in the current ASAS classification criteria for axSpA.

4.1.2 Ankylosis

One of the major concerns of patients with axSpA is progression towards ankylosis of the axial skeleton, which results from ossification of the ligaments and of the costovertebral and sternocostal joints. The first sign of an abnormal posture is loss of lumbar lordosis, followed by thoracic hyperkyphosis and, in severe cases, forward stooping of the neck. Spinal movement is restricted in all planes. The restriction of motion may not be proportionate to the degree of ankylosis because of secondary muscle spasm and other mechanical factors. It is important to detect these abnormal features as early as possible, so that physiotherapy or other appropriate treatments can be initiated.

In patients with restricted chest wall motion, airflow measurements are normal, but vital capacity is decreased and functional residual capacity is increased. Respiratory failure can occur in severe cases. However, ankylosis in the thoracic and lumbar spine is not necessarily linked to severe physical limitations unless the hips are

affected, in which case bending forward is a major problem. Ankylosis at the cervical level often has major physical consequences—for example, in driving, as patients cannot turn their head to view cars alongside them.

4.1.3 Fractures and neurological complications

Although SpA is associated with new bone formation at sites of inflammation, spinal osteoporosis is commonly seen in longstanding SpA, resulting in increased fracture risk (OR = 3.26, 95% CI 1.51 to 7.02). Together with altered biomechanics, this contributes to the high prevalence of fractures, which may occur after even very minimal trauma to the rigid, ankylosed spine (figure 4). The risk of any clinical fracture is increased especially in patients with a history of IBD. Most spinal fractures occur in the lower cervical spine, followed by the thoracic spine and a significant proportion may develop multilevel fractures. Spinal fractures in AS are typically horizontal and may occur through the ossified disc (transdiscal) or the vertebral body (transcorporal) as a result of extension-distraction forces, usually hyperextension injuries. If there continues to be persistent motion at the fracture site, a pseudoarthrosis may develop. The risk of spinal cord injury following spinal fractures in AS is significantly increased and can lead to paraparesis or quadriparesis. One needs to have a high index of suspicion for the possibility of fracture in patients with SpA who present with acute onset of back or neck pain or sudden increased movement range, especially if this follows trauma, even if this sounds trivial. Plain radiography is poorly sensitive due to existing changes from AS and CT and/or magnetic resonance imaging (MRI) may be needed to make the diagnosis.

Spinal osteoporosis is partly due to the lack of mobility as a consequence of the disease, as well as a result of proinflammatory cytokines. Assessment of biochemical markers of bone metabolism has shown diminished bone formation and enhanced bone resorption. Osteoporotic fractures of the thoracic spine contribute to thoracic kyphosis and increased occiput-to-wall distance.

The majority of neurological manifestations of AS are related to spinal cord or nerve compression due to spinal fractures. Neurological involvement may rarely result following atlanto-axial subluxation, although this is far less common than in rheumatoid arthritis. Rarely cauda equina syndrome can present in patients with longstanding AS due to marked ankylosis or dural ectasia. The mechanisms causing dural ectasia (also known as mega dural sac) in AS are not fully understood but may relate to adhesions and fibrosis, likely due to a chronic arachnoiditis, leading to dilation of the dura. Dural ectasia is usually detected on MRI scan and may require surgery in cases with significant neurological compromise.

Figure 4: A) Fracture of the lower part of the thoracic spine (12th thoracic vertebra) and also of the lumbar spine (fourth lumbar vertebra), the latter with an additional aspect of spondylitis and fusion with the third lumbar vertebra in a patient with longstanding ankylosing spondylitis and osteoporosis. (B) Fracture of the middle part of the thoracic spine in a patient with ankylosing spondylitis, causing additional hyperkyphosis to the patient.

4.1.4 Peripheral arthritis

Peripheral arthritis is typically asymmetrical, oligoarticular and involves the lower limbs. Upper limb involvement is typically associated with PsA. A bilateral symmetrical polyarticular presentation is possible, which differs from rheumatoid arthritis in that the distal interphalangeal joints are often affected (the various PsA phenotypes are covered in section 1.1.2).

4.1.5 Dactylitis (sausage digit)

Dactylitis is characteristic of SpA, although not entirely specific and also seen in other rheumatic conditions. It is not as common in AS but is more typical of ReA, PsA or undifferentiated SpA. Unlike synovitis, the swelling is not confined to a joint but involves the whole digit (sausage digit). It is a combination of synovitis, enthesitis, tenosynovitis and soft tissue swelling (figure 5).

Figure 5 Sausage-like digit (dactylitis). (Source: CRI (Club Rhumatismes et Inflammation, <http://www.cri-net.com>).)

4.1.6 Anterior chest wall pain and axial joint involvement (hips and shoulders)

Anterior chest wall pain occurs in about 15% of patients with SpA and up to 45% with axSpA. It is usually the result of sternoclavicular, manubriosternal or costochondral arthritis. As stated above, this can lead to reduced chest expansion.

Arthritis of the hips and shoulders often occurs early in the first 10 years of the disease and affects a third of patients. Hip involvement is commonly bilateral. It is important to check for hip and shoulder joint involvement, as there may be limited range of movement and flexion deformities. Hip involvement often leads to severe destruction and disability. Total hip replacement might be needed at an earlier stage in patients with axSpA who usually also have a reduced range of spinal movement resulting in a severe functional disability (virtually complete loss of forward flexion).

4.1.7 Enthesitis

Painful inflammation of entheses (the sites of attachment of tendons, ligaments, fascia or joint capsules to bone) is the distinguishing pathological feature of SpA. The most typical enthesitis symptom is heel pain (posterior or inferior) related to inflammation of the Achilles' tendon or the plantar fascia insertion. Achilles tendon swelling can be better observed in the standing position from behind. Pain appears in the morning as soon as the patient sets their foot on the floor and slowly improves with ambulation. Heel enthesitis is not painful during sleep but can be very disabling and resistant to standard antirheumatic treatment. Other clinical signs include tenderness of the lateral epicondyles, iliac crest, anterior tibial tuberosity or anterior chest wall. Enthesitis is best visualised by MRI (figure 6) or ultrasonography. It is only detected by radiography after the

ossification process has occurred but it should be noted that calcaneal spurs are not specific for SpA and occur in many otherwise healthy people (figure 7).

Figure 6 Heel enthesitis (MRI findings). (Source: Cofer, <http://www.lecofer.org>.)

Figure 7 Heel enthesitis (ossification). (Source: Cofer, <http://www.lecofer.org>.)

Evaluation of enthesopathy can be undertaken in various ways, traditionally using enthesitis scoring systems such as the Mandel Enthesitis Index, Stoke Enthesitis Index, University of San Francisco Enthesitis Score, Maastricht Ankylosing Spondylitis Enthesitis Score, the Spondyloarthritis Research Consortium of Canada Enthesitis Index, the Berlin Enthesitis Score or the Leeds Enthesitis Index. However, these scoring systems have been criticised for being time consuming and having poor interobserver reliability and face validity. In clinical practice, evaluation generally involves assessment of tenderness at enthesal insertion, MRI and/or ultrasound scans.

4.2 Extra-articular features

4.2.1 Uveitis (iritis or iridocyclitis)

Acute anterior uveitis is the most common extra-articular manifestation of AS, occurring in about 20–30% of patients, with 25–40% of these patients experiencing more than one episode. The incidence is higher in HLA-B27-positive patients. It is important to detect and treat acute anterior uveitis rapidly as visual loss may be irreversible. The condition typically presents with unilateral eye pain, redness, photophobia and increased lachrymation (figure 8). Patients with these signs require urgent examination by an ophthalmologist, and may need specialised treatment (e.g., retro-orbital injections of glucocorticoids in severe cases). With treatment, attacks usually resolve after several weeks- months. The main complication is the occurrence of synechiae. Uveitis that develops with PsA or enteropathic SpA tends to be more chronic and bilateral and often involves posterior elements.

Figure 8 Acute anterior uveitis.

4.2.2 Cardiac manifestations

Cardiac features are rare but may be severe. Heart block is the most frequent manifestation. Aortic insufficiency secondary to an aseptic endocarditis can also be a severe cardiac manifestation of the disease.

4.2.3 Pulmonary involvement

Restrictive lung disease may occur in end-stage disease, as a result of costovertebral and costosternal fusion and limited chest expansion. Apical fibrosis may occur in severe disease and this may become colonised with bacteria or fungi such as *Aspergillus*.

4.2.4 Renal involvement

IgA nephropathy has been reported in AS in a few case reports. Amyloidosis is a very rare complication in severe longstanding disease. Renal deficit is more commonly a result of NSAID related toxicity.

4.2.5 Gastrointestinal involvement

Inflammatory lesions in the gut are common and can cause diarrhoea, which is usually accompanied by blood and mucus. Loss of weight is common. IBD may or may not have already been diagnosed in these patients. The prevalence of IBD in AS has been reported to range between 6-15%. Furthermore, colonoscopic mucosal biopsy shows that subclinical microscopic inflammatory lesions are seen in about 60% of SpA patients who have no gastrointestinal symptoms or clinically obvious IBD. Follow-up studies of such patients indicate that 6% will develop IBD. About 28–35% of patients with enteropathic arthritis have axial disease: 10–20% have sacroiliitis alone, 7–12% have spondylitis and 10% have the classic features of SpA. The axial radiology is similar to that of AS, characterised by symmetrical bilateral sacroiliitis. The onset of axial involvement often precedes that of bowel disease.

4.2.6 Dermatological manifestations

Dermatological manifestations are common but are usually related to a specific disorder such as psoriasis or ReA. Psoriasis is seen in 20–40% of patients with SpA. Nail lesions are a common feature in patients with rheumatological manifestations (Figure 9).

Figure 9: Nail lesions in a patient with psoriatic disease. Oil dyschromias, onycholysis and pitting can be observed. [Source: CRI (Club Rhumatismes et Inflammation, <http://www.cri-net.com/>)]

4.3 Comorbidities

When considering comorbidities one has to consider mainly cardiovascular (CV) disorders, hypertension and osteoporosis (see section 4.1.3 Fracture). The mortality rate in patients with AS is increased twofold in comparison with that in the general population, mainly owing to an increased CV risk. Although specific CV disorders (valvular disease and conduction disturbances) occur more frequently in AS, accelerated atherosclerosis disease due to chronic systemic inflammation probably also contributes to the increased CV risk of these patients. AS is also associated with an increased risk of hypertension.

5 Laboratory features

No laboratory tests are diagnostic for SpA. Erythrocyte sedimentation rate and C-reactive protein (CRP) are raised in 40% of patients. Increased CRP is one of the features of SpA used in the ASAS classification for axSpA, but must be present with other features. Patients with non-radiographic axSpA who have increased CRP levels have an increased risk of further structural progression in the SI joints, and developing AS. On the other hand, increased CRP levels are also predictors for a good response to treatment with TNF α blockers (OR = 2.8, 95% CI 1.3 to 5.7).

A mild normochromic normocytic anaemia of chronic disease may be present in patients with axSpA. Alkaline phosphatase may also be raised but this does not correlate with disease activity.

HLA-B27 is present in >90% of patients with AS. However, HLA-B27 by itself has no diagnostic value since it is found in up to 8% of healthy European individuals; it is therefore more helpful in populations with lower HLA-B27 prevalence. Determining HLA-B27 status is not mandatory in clinical assessment but is especially helpful for classifying patients who have negative imaging. With the new ASAS classification criteria for axSpA, a patient with a 3-month history of back pain that started before the age of 45 years can be classified as having SpA if HLA-B27 is positive and two other SpA features are present. The diagnosis of SpA is unlikely when imaging and HLA-B27 are both negative.

6 Imaging

EULAR has recently published recommendations for the use of imaging in the diagnosis and management of SpA in clinical practice (Mandl et al. *Ann Rheum Dis.* 2015;74:1327-39).

6.1 Plain radiographs

Plain radiographs of the spine, SI joints and peripheral joints can show various structural changes. However, they are unhelpful in the early, 'non-radiographic' stage because structural changes reflect the consequences of inflammation rather than inflammation itself (see section 6.2 MRI). Radiographic sacroiliitis is the hallmark

of AS and takes several years to become visible on plain radiographs. While a number of specific sacroiliac views have been proposed, these x-rays can be difficult to interpret for those unfamiliar with these views. Therefore, standard antero-posterior views of the pelvis are generally recommended for imaging the SI joints as this modality also allows assessment of the hip joints, which are frequently affected in AS. The earliest visible changes include blurring of the cortical margins of the subchondral bone, erosions and sclerosis (figure 10). As erosions progress, the joint space appears wider and then fibrous, until bony ankylosing obliterates the joint. Joint changes usually become symmetrical during the course of the disease. Radiographic sacroiliitis can be graded according to the New York grading system as follows: grade I, suspicious; grade II, evidence of erosion and sclerosis; grade III, erosions, sclerosis and early ankylosis; and, finally, grade IV, total ankylosis.

The modified New York criteria for classification of AS (box 7) combine different clinical criteria with evidence of definite structural changes on conventional radiographs. However, these criteria focus mainly on the SI joints (both clinically and on radiographs) and the spine (only clinically) and do not include any extra-articular manifestations of the disease. The sensitivity of the modified New York criteria increases with disease duration (sensitivity 0% for a disease duration of 2 years vs 60% for a disease duration of >10 years). The delay before detecting radiological sacroiliitis might explain these results. As stated above, although the modified New York criteria are sensitive, they cannot detect mild, undifferentiated or early forms of the disease.

Figure 10 Radiological sacroiliitis in ankylosing spondylitis.

Spinal X-ray findings typically show squaring of the vertebrae secondary to erosions of the superior and inferior margins of these bodies (figure 11). Vertebral enthesitis may cause sclerosis of the upper and lower vertebral bodies, which appears as the formerly called 'shiny corners'. Annulus fibrosus ossification leads to

syndesmophyte formation and over time bridging of these syndesmophytes results in a bamboo spine (figure 12). Structural damage of the spine can be scored using the modified Stoke Ankylosing Spondylitis Spine Score (mSASSS) (figure 13).

Figure 11 (A) Radiological lumbar spinal ankylosis; (B) normal spine. (Source: Cofer, <http://www.lecofer.org>.)

- **M – SASSS**
 - Anterior site of the vertebra
 - C2 to T1, T12 to S1
 - Score =
 - 0 = normal
 - 1 = erosion, sclerosis or syndesmophyte
 - 2 = syndesmophyte
 - 3 = bridging syndesmophytes
 - Range 0 - 72

Wanders A *et al*. *Arthritis Rheum* 2004;50:2612-32
Wanders A *et al*. *Ann Rheum Dis* 2004;63:1601-4

AS and enteropathic arthritis typically exhibit bilateral symmetrical sacroiliitis and continuous syndesmophytes, while ReA and PsA characteristically exhibit asymmetrical sacroiliitis and discontinuous spondylitis.

Radiographs of other areas such as the heel or hip might show evidence of enthesitis.

6.2 MRI

MRI can detect inflammatory lesions long before definite lesions are visible on plain radiographs. The ASAS criteria for axSpA include inflammation in the SI joints seen on MRI as one of the major entry criteria. When clinical suspicion of early SpA is high but standard radiography of the SI joints is normal or shows only equivocal changes, MRI can produce excellent evidence of sacroiliitis and enthesitis (figure 14). The preferred imaging sequences are T2-weighted fat-suppressed fast spin-echo, for chronic fatty changes, and short-tau inversion recovery (STIR) sequences for assessment of bone marrow oedema (BMO), which represents a sign of inflammation. The regular use of gadolinium or contrast is no longer recommended for routine diagnostic scans in axSpA.

Figure 14A Sacroiliitis (MRI findings on STIR sequence). STIR, short-tau inversion recovery. (Source: Cofer, <http://www.lecofer.org>.)

Figure 14B Spondylitis (left image, STIR MRI) and fatty degeneration (postinflammatory, right image, T1-weighted MRI). STIR, short-tau inversion recovery.

Box 7 Modified New York criteria for ankylosing spondylitis (AS)

Diagnosis

- Clinical criteria
 - Low back pain and stiffness for more than 3 months which improves with exercise but is not relieved by rest
 - Limitation of motion of the lumbar spine in both the sagittal and the frontal planes
 - Limitation of chest expansion relative to normal value, corrected for age and sex
- Radiological criterion (x-ray)
 - Sacroiliitis grade ≥ 2 bilaterally or sacroiliitis grade 3–4 unilaterally

Grading

- Definite AS if the radiological criterion is present with at least one clinical criterion
- Probable AS if:
 - Three clinical criteria are present
 - The radiological criterion is present without any signs or symptoms fulfilling the clinical criteria

Adapted from van der Linden et al, Arthritis Rheum 1984;27:361–8.

Box 8 ASAS classification criteria for axSpA

Patients with back pain ≥ 3 months and age at onset <45 years

- **Imaging arm:** *Sacroiliitis on imaging** plus ≥ 1 SpA feature** or
- **Clinical arm:** *HLA-B27* plus ≥ 2 other SpA features**

*Sacroiliitis on imaging = definite radiographic sacroiliitis according to the modified New York criteria *or* positive sacroiliac MRI

**SpA features:

- Inflammatory spinal pain
- Arthritis
- Enthesitis (heel)
- Uveitis
- Dactylitis
- Psoriasis
- Crohn's/colitis
- Good response to NSAIDs
- Family history of SpA
- HLA-B27
- Elevated CRP

- Dactylitis
- IBP (ever)
- Family history of SpA

ASAS, Assessment of SpondyloArthritis international Society; IBP, inflammatory back pain; SpA, spondyloarthritis.

MRI evidence of sacroiliitis has been incorporated in the ASAS classification criteria for axSpA (Box 8) that are covered in more detail in Section 7. The ASAS/OMERACT (Outcome Measures in Rheumatology Clinical Trials) MRI working group has proposed a definition of a 'positive' MRI (Rudwaleit et al, 2009a*). This definition should be applied for the imaging feature 'sacroiliitis by MRI' of the ASAS classification criteria for axSpA.

According to this definition the following findings are required:

- Active inflammatory lesions of the SI joints, BMO (on STIR) must be clearly located in typical anatomical areas (subchondral or periarticular bone marrow).
- When a solitary BMO lesion is seen, this should be present on at least two consecutive slices.
- When more than one BMO lesion is seen on one slice, documentation of inflammation by using one single slice only is sufficient.
- The presence of synovitis, enthesitis or capsulitis without concomitant BMO/osteitis is not sufficient for diagnosis.

However, since BMO can also be found in patients with mechanical low back pain, but moderate or severe lesions are only found in patients with IBP, there is definite need for experience and consideration of pre-test probability when interpreting MRI of the SI joints. Also, further study is needed to specify the size and severity of the lesions in order to improve the specificity of MRI, so these definitions are likely to evolve in future.

Furthermore, a definition of a 'positive' MRI of the spine, has been also recently proposed by ASAS (Hermann et al, 2012*). According to this definition, evidence of spondylitis in three or more vertebral sites is highly suggestive of inflammatory lesions related to axSpA, while evidence of fatty deposition in several vertebral

sites (at least 5) is highly suggestive of post inflammatory lesion-related axSpA. These lesions should preferably be located at the edges of the vertebrae, independently of whether these edges are in the anterior or the posterior part of the vertebral body.

6.3 Other imaging modalities

Bone scintigraphy is not recommended for identification of sacroiliitis or spondylitis in the context of axSpA owing to the associated radiation exposure and its low sensitivity (50–55%) and specificity (<80%).

Furthermore, ultrasound of SI joints is also not frequently used in daily practice owing to lack of standardisation of both its use and interpretation of findings, while computed tomography (CT) seems to have only an additional value in detection of structural changes but is also associated with higher radiation exposures, which is an important limiting factor for its use in daily routine.

6.4 Differential diagnosis of the radiographic findings

The differential diagnosis of low back pain includes various situations. Some of these, like osteitis condensans ilii (OCI) and diffuse idiopathic skeletal hyperostosis (DISH) share similar radiographic characteristics with AS.

OCI affects mainly but not always women who have given birth and its prevalence is estimated to be about 0.9–2% of the general population. Its aetiology remains largely unknown but mechanical stress seems to be the main factor. It is a non-inflammatory condition and typically the patients are HLA-B27 negative. Radiologically, it is characterized by triangular sclerosis – usually, but not always, bilaterally - in the iliac bone on x-ray, without erosions or sacroiliac joint narrowing. Lack of involvement of the sacrum or joint space narrowing is usually diagnostic.

DISH (also known as Forestier's disease) is most common among middle-aged/elderly people and rare before the age of 40. DISH is characterised by ossification of soft tissues, including ligaments and tendons, of joint capsule and of contiguous vertebrae, leading to bony bridges in the spine. Despite the often striking radiographic changes, which may resemble those seen in the spine in AS, patients with DISH often have disproportionately mild symptoms or functional impairment. The aetiology of DISH is unknown but it is correlated with obesity and metabolic disorders like diabetes mellitus. There are currently no treatments available for this, apart from standard analgesia for back pain, if required. Differentiation of DISH from AS is based on clinical (milder symptomatology) and radiological features. There are a number of radiographic criteria used to diagnose DISH which include flowing ossification/calcification of the anterior longitudinal ligament, preservation of intervertebral disc height in affected areas (differentiating this from pure degenerative spinal disease) and relative sparing of the SI joints (differentiating this from AS). While SI joint capsule ossification and mild narrowing or sclerosis may be observed in DISH, this is usually in the upper portion of the joint with no erosions or bony ankylosis as typical for AS.

7 Classification criteria

The SpA conditions are heterogeneous multisystem disorders with no single ‘gold standard’ clinical, laboratory, pathologic or radiologic feature to confirm the diagnosis. A number of criteria have therefore been developed to support clinical practice and research. It should however be noted that there are currently no diagnostic criteria (i.e. to be applied in clinic where the *a priori* diagnosis is unknown) for SpA and that all the current criteria for axSpA and SpA are classification criteria (designed to be applied where the *a priori* diagnosis is suspected in order to create more homogenous cohorts for research purposes). There are many important differences between diagnostic and classification criteria. Therefore, while classification criteria can be useful in clinical practice, they cannot simply be applied using a “check box” process as a diagnosis of axSpA and SpA in clinic also requires exclusion of other potential causes for symptoms and findings, which is usually best done by a clinician with expertise in these conditions.

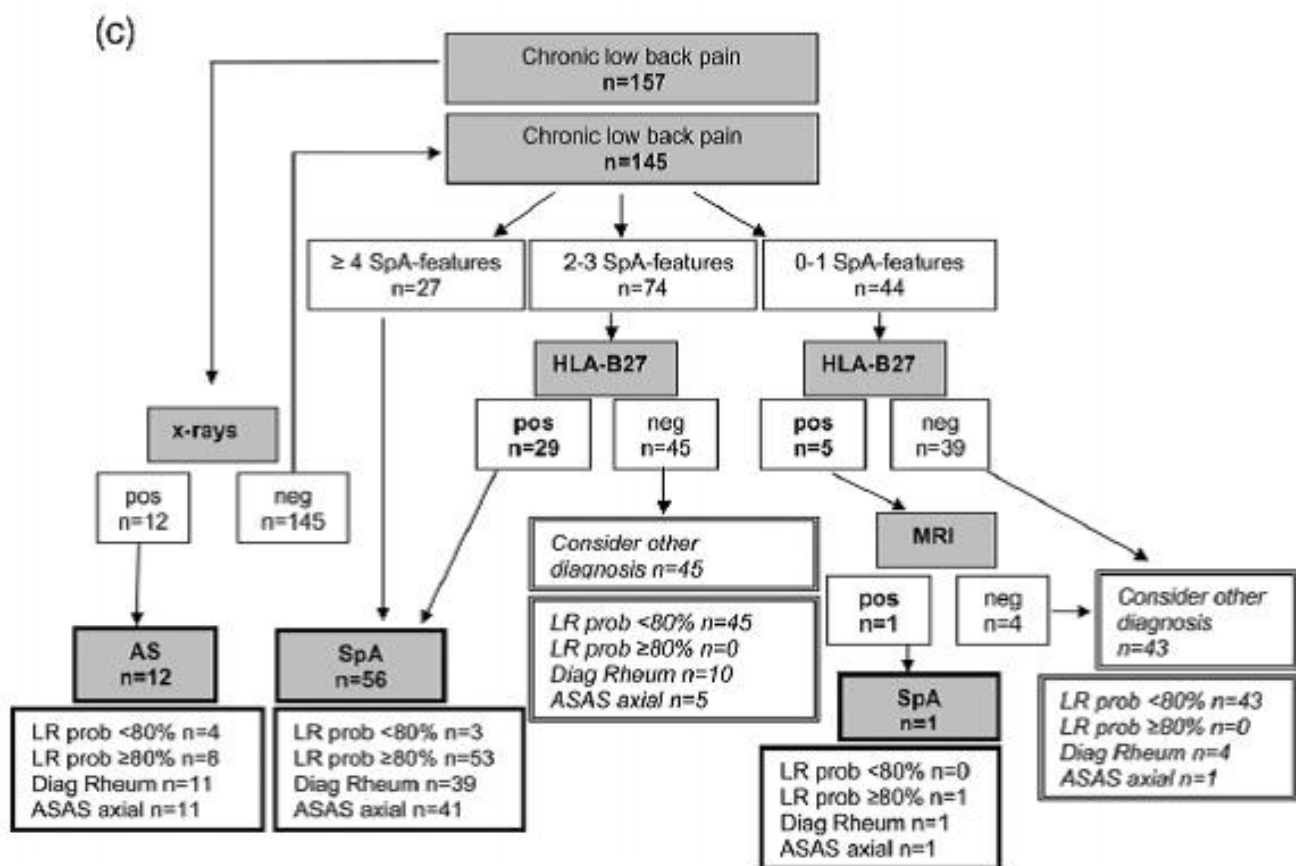

The new validated ASAS classification criteria for axSpA (box 8) and for peripheral SpA and SpA in general (box 9) are a major step forward (Rudwaleit et al, 2009b*; Rudwaleit et al, 2011*). It is now possible to diagnose axSpA earlier. The ASAS criteria for axSpA are applied in patients with predominantly axial symptoms with or without peripheral manifestations, while the criteria for peripheral SpA in general have been developed for patients who present with predominantly symptoms of peripheral arthritis, enthesitis or dactylitis. The ASAS classification criteria for axSpA require a history of chronic back pain (pain duration ≥ 3 months) and an age of onset of < 45 years as entry criteria. Patients can then fulfil the axSpA criteria either via the imaging arm, with evidence of sacroiliitis on X-ray or MRI in addition to at least one typical clinical SpA feature, or via the clinical arm with the presence of HLA-B27 in addition to at least two other typical clinical SpA features. With this set of criteria, patients can be still classified as AS when they present with established radiographic changes in the SI joints, or as non-radiographic axSpA when such changes have not yet occurred but other entry criteria (see above and box 8) are present. The introduction of this new concept has led to an increasing interest in patients with non-radiographic axSpA, leading to clinical trials and subsequent licensing of therapies for this indication. The ASAS classification criteria have a sensitivity of 82.9% and a specificity of 84.4%.

The most significant change in the criteria, as compared with former criteria sets, is the inclusion of inflammatory activity detected by MRI. On the other hand, normal MRI results do not necessarily exclude a classification as SpA, which can still be made on the basis of clinical findings. In such a case, and as mentioned above, the presence of HLA-B27 plus two other SpA features is useful for classification. Another important difference of the new ASAS criteria is that IBP is no longer a compulsory criterion but is being considered as one of the typical clinical SpA features, among all others.

Patients with peripheral symptoms without major axial involvement can be classified with the ASAS classification criteria for peripheral SpA (Box 9). These require a history of arthritis, enthesitis or dactylitis in addition to SpA features.

As mentioned previously, there are no diagnostic criteria for SpA, which means that in daily clinical practice one might have to adopt a more flexible approach. A proposed clinical diagnostic tree is shown in figure 15.

Figure 15 Diagnostic pathway for ankylosing spondylitis and spondyloarthritis in patients presenting with chronic back pain (decision tree). AS, ankylosing spondylitis; ASAS, Assessment of SpA international Society; LR, likelihood ratio; SpA, spondyloarthritis. (Reproduced from van den Berg et al, *Ann Rheum Dis* 2013;72:1646–53.)

8 Treatment

Treatment with NSAIDs and exercise is recommended as first-line therapies in patients with SpA. For those patients who still have active disease the introduction of TNF inhibitors (TNFi) was a major advance in the management of axSpA. The main principles of the treatment of patients with SpA is published by ASAS in the ASAS/EULAR recommendations for the management of AS (Braun et al, 2011*). One important principle in the treatment of patients with SpA is the need for a combination including pharmacological and non-pharmacological treatment options. The treating physician should tailor the treatment of patients according to

prognostic factors (see section 9.3, Can we predict the further course of the disease?) and to the general clinical status, including comorbidity.

8.1 NSAIDs

NSAIDs are recommended as first-line drugs for patients with axSpA. If taken in appropriate dosages, they are efficacious for the relief of pain and stiffness in up to 60–70% of the patients. Long-acting NSAIDs could be prescribed at bed time to relieve early morning stiffness. There is no significant difference in efficacy between short-acting and long-acting agents or between Cox-2-selective and non-selective agents. Up to 15% of patients with active AS treated with a full dose of an NSAID may even reach a status of partial remission. The question of whether it is advisable to recommend continuous treatment with NSAIDs even in, or after reaching, a status of low disease activity is still a matter of discussion. The effect of NSAIDs on inflammatory activity (CRP, BMO) or on the radiographic progression of patients with axSpA is still not clear.

8.2 Anti-TNF therapy

The major advance in the treatment of patients with AS was the approval of anti-TNF blockers at the beginning of the 21st century. Anti-TNF blockers should be prescribed according to the international ASAS recommendations (van der Heijde et al, 2011*) (table 2) in conjunction with national guidelines. These recommendations give detailed information for patient selection, assessment of disease and assessment of response when using these compounds. It is important to note that these recommendations specifically relate to patients with axSpA. For treatment with anti-TNF agents, patients need to have increased disease activity, which is defined as Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) ≥ 4 (on a 0–10 scale) despite previous treatment with at least two NSAIDs over a period of 4 weeks. There is no evidence to support the obligatory use of disease-modifying antirheumatic drugs (DMARDs) before starting anti-TNF therapy.

It is recommended that the response to anti-TNF therapy is assessed 3 months after starting treatment. A decrease of disease activity (as measured by the BASDAI) of at least 50% as compared with previous treatment (BASDAI-50 response) or an absolute BASDAI change of ≥ 2 units (on a 0–10 scale) in addition to an expert opinion (based on improvement in CRP, MRI inflammation or clinical examination) are considered parameters for continuing treatment. Currently adalimumab, etanercept, certolizumab and golimumab are licensed for use in both AS and non-radiographic axSpA (with positive MRI and/or elevated CRP) while infliximab (and therefore also its biosimilar) is only licensed for AS. The exact role and positioning of biosimilars in the treatment of axSpA in clinical practice remains to be seen and will ultimately be influenced by cost, demonstration of sustained efficacy and long-term safety.

Table 2 2010 Update of the international ASAS recommendations for the use of anti-TNF agents in patients with SpA

Patient selection	Recommendation
Diagnosis	Patients fulfilling modified New York criteria for definitive AS or the ASAS criteria for axSpA
Active disease	<ul style="list-style-type: none"> • Active disease for ≥ 4 weeks • BASDAI ≥ 4 (0–10) and a positive expert opinion
Treatment failure	<ul style="list-style-type: none"> • All patients should have had adequate therapeutic trials of at least two NSAIDs. An adequate therapeutic trial is defined as at least two NSAIDs over a 4-week period in total at a maximum recommended or tolerated anti-inflammatory dose unless contraindicated • Patients with predominantly axial manifestations do not have to take DMARDs before anti-TNF treatment can be started • Patients with symptomatic peripheral arthritis should have an insufficient response to at least one local steroid injection if appropriate and should normally have had an adequate therapeutic trial of a DMARD, preferably sulfasalazine • Patients with symptomatic enthesitis must have had appropriate local treatment which has failed
Assessment of disease	ASAS core set for daily practice and BASDAI
Assessment of response	
Responder criteria	BASDAI: 50% relative change or absolute change of 2 units (on 0–10 scale) and expert opinion in favour of continuation
Time of evaluation	After at least 12 weeks

AS, ankylosing spondylitis; ASAS, Assessment of SpA international Society; axSpA, axial spondyloarthritis; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; DMARDs, disease-modifying antirheumatic drugs; NSAIDs, non-steroidal anti-inflammatory drugs; SpA, spondyloarthritis; TNF, tumour necrosis factor.

Patients with high disease activity, short disease duration, no structural lesions and increased CRP are more likely to benefit from anti-TNF medication than patients with longstanding disease, extensive structural changes and poor functioning before treatment initiation. Overall, the response rates to anti-TNF treatment in clinical practice appear better than those reported in the phase III clinical trials, which may relate at least in part to differences in outcome measures used in these settings. Even in patients with complete ankylosis of the spine, this treatment has substantial clinical efficacy on symptoms. There is no evidence of differences in the efficacy of the various TNFi approved so far. The initial phase III open-label extension studies in AS did not report any reduction in radiographic progression when compared to historical AS controls. However, more recent observational studies and longer follow-up of study participants, have suggested that TNF inhibitors may indeed slow radiographic progression, particularly in earlier disease. There is now also increasing data from registries and observational studies to support the use of sequential TNF blockers for axSpA where patients fail to respond to a particular TNF inhibitor. Withdrawal of TNF inhibitors in patients in apparent remission is not recommended as several studies have shown that the majority of patients will relapse rapidly,

with most flaring up within the first 4-10 weeks of discontinuation. Intermittent or 'on-demand' dosing has been shown to only marginally reduce costs, at the expense of worse clinical outcomes, so is also not recommended. However, there is increasing interest in reducing or tapering the dose or frequency of TNF inhibitors in patients in remission, with several ongoing studies evaluating this approach.

8.3 Anti-IL-23/-17 drugs

The IL-23/-17 axis has been increasingly implicated in the pathogenesis of SpA, leading to the development of therapeutic agents targeting IL-23 and IL-17. Amongst them, the best studied are: Ustekinumab, a fully human monoclonal antibody against the p40 subunit of both IL-12 and IL-23, and Secukinumab, a fully human monoclonal antibody against IL-17A.

Both ustekinumab and secukinumab are already licensed and established in clinical practice for the treatment of active psoriasis and PsA. The skin responses in the skin with IL-17 inhibition have been particularly impressive. Both these agents have demonstrated efficacy in PsA in both TNF-naïve and TNF-experienced patients.

Recent phase III studies have demonstrated the efficacy of secukinumab in active AS, leading to approval by the regulatory agencies. Several other anti-IL-17 agents are also in development for AS and a range of other SpA conditions. Early phase studies suggest potential efficacy of ustekinumab in AS, with the results of phase III studies awaited. Agents specifically targeting IL-23, but not IL-12, directly or via the p19 subunit, are also in development. Overall, these agents appear to have an acceptable safety profile, although their long-term safety in SpA remains to be established.

8.4 DMARDs

Data on the use of DMARDs in patients with AS did not show an effect on axial symptoms, so their use for axial disease is not recommended where biologic agents are available. The majority of the studies suggest a limited efficacy of sulfasalazine in patients with peripheral SpA and in the prevention of anterior uveitis. One head-to-head trial comparing sulfasalazine with a TNF blocker showed that TNF blockade is more efficacious in achieving an ASAS20 response at week 16 than sulfasalazine (75.9% vs 52.9%, $p < 0.0001$)

8.5 Non-pharmacological treatment

The cornerstone of non-pharmacological treatment is regular exercise and patient education. It has been shown that regular exercises are effective in reducing pain and preserving functioning. Overall, supervised exercises are more effective than home exercises.

8.6 Surgery

Surgery might be required in patients with AS with hip involvement, severe spinal deformity or vertebral fracture. Around 5% of patients will undergo a total hip arthroplasty, while around 50% of these patients will need bilateral hip replacement during the course of their disease. Chronic knee disease may also necessitate knee replacement in a minority. The restricted mobility and hyperkyphosis of the spine may lead to loss of the ability to keep the eyes and head upwards, or being able to look horizontally. Patients with such severe deformities can benefit from a spinal corrective osteotomy. Such procedures should only be performed in experienced centres. As stated above, patients with AS have an increased risk of vertebral fractures but not of non-vertebral fractures. In most cases the occurrence of a spinal fracture is an acute clinical situation that may be associated with neurological symptoms. Although not all patients need to be operated on, physicians should consider consulting an experienced surgeon when even 'silent' fractures are suspected.

9 Assessment/monitoring

For both assessment and monitoring, one has to consider systematically the four potential clinical presentations of axSpA: axial involvement, peripheral arthritis, enthesopathy and extra-articular features. According to the variable disease course, the clinical presentation of the patient should be the key feature for disease monitoring. Monitoring is based on the clinical presentation, and the tools used for evaluating the severity of axial involvement are similar, and independent of the SpA subgroup. Principles for monitoring patients with AS are defined in the ASAS core set (table 3). The ASAS recommendations for the management of AS do not specify the time frame in which patients have to visit the treating physician. It is advisable that a patient with a new diagnosis or with a high disease activity should be seen more often than a patient with a low disease activity. In general, spinal X-ray examinations do not need to be repeated more frequently than every 2 years unless indicated in individual cases as a result in altered symptoms, such as concern about a fracture. Each change in the disease course should be evaluated carefully by the treating physician.

Table 3 ASAS core set (Adapted from van der Heijde D et al, *J Rheumatol* 1999;26:951–4)

Domain	Instrument
Physical function*	BASFI or Dougados Functional Index
Pain*	VAS/NRS past week in spine, at night, due to AS and VAS/NRS past week, in spine due to AS
Spinal mobility*	Chest expansion and modified Schober and occiput-to-wall distance and lateral spinal flexion
Patient global assessment*	VAS/NRS past week
Morning stiffness*	Duration of morning stiffness in spine past week
Fatigue*	VAS/NRS past week
Peripheral joints and entheses†	Number of swollen joints (44 joint count). Validated enthesitis indexes
Acute phase reactants†	ESR
Spine radiographs‡	Anteroposterior + lateral lumbar and lateral cervical spine and X-ray examination of pelvis to visualise sacroiliac joint and hips)
Hip radiographs‡	As above

*Included in core set for SMARDs/physical therapy.

†Included in core set for SMARDs/physical therapy and clinical record keeping.

‡Included in core set for SMARDs/physical therapy and DC-ART.

AS, ankylosing spondylitis; ASAS, Assessment of SpondyloArthritis international Society; BASFI, Bath AS Functional Index; DC-ART, disease-controlling antirheumatic therapy; ESR, erythrocyte sedimentation rate; NRS, numerical rating scale; SMARDs, symptom-modifying antirheumatic drugs; VAS, Visual Analogue Scale.

ASAS has issued recommendations about the use of different assessment tools covering the various domains of disease activity, which are largely determined by the patient's level of treatment (table 3).

Appropriate assessment tools are needed, depending on the clinical pattern of the disease. Table 4 summarises the different clinical patterns in patients with SpA.

Table 4 Evaluation of activity of different clinical patterns of SpA

Axial involvement	Peripheral arthritis	Enthesopathy	Extra-articular features
Night pain	Night pain	Pain	Acute anterior uveitis
Morning stiffness	Morning stiffness	Functional impairment	
CRP	Swollen joint count, CRP		
Pain	Pain	Enthesopathy index	Psoriasis
Functional impairment	Tender joint count Functional impairment		IBD
MRI	US, MRI	US, MRI bone scan	

CRP, C-reactive protein; IBD, inflammatory bowel disease; MRI, magnetic resonance imaging; SpA, spondyloarthritis; US, ultrasonography.

In patients with axial involvement, the degree of both night pain and spinal pain during the day is measured using either a Visual Analogue Scale (VAS) or a Numerical Rating Scale (NRS). Morning stiffness in the lumbar spine should be evaluated for both duration and severity. Functional impairment is evaluated using the Bath AS Functional Index (BASFI) (box 10). The score ranges from 0 to 10, where higher values indicate worse

functioning. All the above tools are patient reported and considered subjective. When using the VAS, a value >4 on a scale from 0 to 10 is usually considered as reflecting 'active' disease.

Box 10 Bath Ankylosing Spondylitis Functional Index (BASFI): evaluation of functional impairment

Please indicate your level of ability with each of the following activities during the past week (difficulty is assessed on a VAS/NRS ranging from "easy" to "impossible")

- Putting on your socks or tights without help or aids (e.g., sock aids)
- Bending forward from the waist to pick up a pen from the floor without an aid
- Reaching up to a high shelf without help or aids (e.g., helping hand)
- Getting up out of an armless dining room chair without using your hands or any other help
- Getting up off the floor without help from lying on your back
- Standing unsupported for 10 min without discomfort
- Climbing 12–15 steps without using a handrail or walking aid (one foot each step)
- Looking over your shoulder without turning your body
- Doing physically demanding activities (e.g., physiotherapy exercises, gardening or sports)
- Doing a full day's activities whether it be at home or at work

NRS, numerical rating scale; VAS, visual analogue scale

The main question in daily practice is whether it is mandatory to employ objective methods to evaluate such activity before considering a new treatment, such as an anti-TNF agent. The only current non-subjective instruments reflecting axial disease activity are serum CRP (raised in up to 40% of patients) and the presence of inflammatory lesions on MRI of the spine and/or SI joints.

In peripheral arthritis, disease activity evaluation is similar to that used in rheumatoid arthritis—for example, number of tender joints, number of swollen joints, CRP, etc. Enthesitis assessments may also be used in patients with enthesal involvement. There is no consensus definition of a peripheral 'active' disease. However, the presence of at least three swollen joints is usually considered to reflect active disease, particularly when associated with an increased CRP.

9.1 Composite index to assess disease activity

Besides the different instruments facilitating disease activity assessment of the separate clinical presentations, instruments (e.g., a composite index) have been proposed to allow a general evaluation.

The BASDAI (box 11) is simple to use since it comprises only six questions related to:

The BASDAI score ranges from 0 to 10, higher values indicating more active disease. A score >4 is considered as the threshold above which a disease status can be considered as active. A change of at least 50% in the BASDAI is usually considered as reflecting a clinically relevant improvement.

Box 11 Bath Ankylosing Disease Activity Index: evaluation of disease activity

Patients are asked to answer each of the following relating to the *past week* (measured on VAS/NRS)

- How would you describe the overall level of fatigue/tiredness you have experienced? (assesses fatigue)
- How would you describe the overall level of ankylosing spondylitis neck, back or hip pain you have had? (assesses axial involvement)
- How would you describe the overall level of pain/swelling in joints other than the neck, back or hips you have had? (assesses peripheral joint involvement)
- How would you describe the overall level of discomfort you have had from any areas tender to touch or pressure? (assesses enthesopathy)
- How would you describe the overall level of morning stiffness you have had from the time you wake up? (assesses morning stiffness/inflammation)
- How long does your morning stiffness last from the time you wake up? (assesses morning stiffness/inflammation)
-).

NRS, numerical rating scale; VAS, visual analogue scale

The BASDAI score ranges from 0 to 10, higher values indicating more active disease. A score >4 is considered as the threshold above which a disease status can be considered as active. A change of at least 50% in the BASDAI is usually considered as reflecting a clinically relevant improvement.

9.1.1 AS Disease Activity Score (ASDAS)

More recently, another composite index taking into account some questions from the BASDAI (Q 2 total back pain, Q3 peripheral pain and Q6 morning stiffness), plus the patient global assessment and biological markers of inflammation (either CRP or erythrocyte sedimentation rate) has been proposed (box 12). The ASDAS has been extensively validated. It has been shown to be reliable, discriminative and sensitive. The cut-off points between the disease activity states are: inactive disease ≤ 1.3 , moderate 1.3–2.0, high 2.1–3.5 and very high ≥ 3.5 . The ASDAS cut-off point for clinically important improvement is ≥ 1.1 and the cut-off point for a major improvement is ≥ 2.0 from baseline. However, the ASDAS has still not been evaluated for use in daily practice, whereas the BASDAI is the standard measuring instrument used in clinics for disease activity in axSpA.

Box 12 Evaluation of the activity of the disease – ASDAS-CRP/ESR**ASDAS-CRP***

$0.21 \times \text{Total back pain} + 0.110 \times \text{Patient global} + 0.073 \times \text{Peripheral pain/swelling} + 0.058 \times \text{Duration of morning stiffness} + 0.579 \times \ln(\text{CRP} + 1)$

ASDAS-ESR*

$0.113 \times \text{Patient global} + 0.293 \times \sqrt{\text{ESR}} + 0.086 \times \text{Peripheral pain/swelling} + 0.069 \times \text{Duration of morning stiffness} + 0.079 \times \text{Total back pain}$

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

Source: Lukas et al, Ann Rheum Dis 2009;68:18–24.

ASAS has proposed composite indices for monitoring disease activity in clinical trials, although these are designed to be applied in the group setting rather than for individuals, so are of unproven utility in daily

clinical practice. The key responder (ASAS 20 improvement) and remission (ASAS partial remission) criteria used in clinical trials are shown on Box 13 and 14, respectively.

Box 13 ASAS20 improvement criteria

Improvement of at least 20% and absolute improvement of at least 10 on a 0–100 scale in at least three of the following domains:

- Patient global (VAS (0–100))
- Pain (VAS global, past 2 days (0–100))
- Function (BASFI (0–100))
- Inflammation
 - o First choice—two last questions of the BASDAI
 - o Second choice—morning stiffness duration with a maximum of 120 mm on a 0–100 scale

And no deterioration (of at least 20% and absolute deterioration of at least 10 on a 0–100 scale) in the remaining domain.

ASAS, Assessment of SpondyloArthritis international Society; BASDAI, Bath AS Disease Activity Index; BASFI, Bath AS Functional Index; VAS, Visual Analogue Scale.

9.2 What is disease severity?

The term ‘severity’ is often used but not defined for patients with AS. Severity as understood by experts contains all the different aspects of the disease (disease activity, damage, reduced mobility, reduced physical function, reduced social participation). Such ‘severity’ can be assessed using different approaches, such as, functional impairment, limited range of motion, hip involvement, radiological damage, quality of life and even job loss or death. Here, we focus on the four measures that are mainly related to SpA.

9.2.1 Functional impairment

Functional impairment can be related to both the activity and the severity of the disease. Several available instruments (Bath AS Functional Index (BSAFI), Health Assessment Questionnaire (HAQ), Western Ontario and

McMaster Universities osteoarthritis index, etc.) can be used depending on the clinical presentation of SpA (e.g. peripheral versus axial).

9.2.2 Range of motion

The most commonly used instrument to measure mobility in clinical trials is the Bath AS Metrology Index (BASMI), a composite index combining information from five different assessments: cervical rotation (figure 16), tragus-to-wall distance (figure 17), spinal lateral flexion (figure 18), lumbar flexion (modified Schober's test) (figure 19) and intermalleolar distance (figure 20). Three different definitions have been published: the 2-step definition, the 10-step definition and the linear definition. ASAS recommends the 10-step definition or the linear definition. Table 5 shows details of the BASMI.

Figure 16 Cervical rotation using a goniometer.

Figure 17 Tragus-to-wall distance.

Figure 18 Spinal lateral flexion.**Figure 19 Lumbar flexion (modified Schober's test).****Table 5 Bath Ankylosing Spondylitis Mobility Index (BASMI): evaluation of spinal mobility (Adapted from Jenkinson et al, J Rheumatol 1994;21:1694–8 and van der Heijde et al, Ann Rheum Dis 2008;67:489–93)**

If:	Then score =										
	0	1	2	3	4	5	6	7	8	9	10
Lateral lumbar flexion (cm)	≥20	18–20	15.9– 17.9	13.8– 15.8	11.7– 13.7	9.6– 11.6	7.5– 9.5	5.4– 7.4	3.3– 5.3	1.2– 3.2	≤1.2
Tragus-to-wall distance (cm)	≤10	10– 12.9	13– 15.9	16– 18.9	19– 21.9	22– 24.9	25– 27.9	28– 30.9	31– 33.9	34– 36.9	≥37
Lumbar flexion (modified Schober) (cm)	≥7	6.4– 7.0	5.7– 6.3	5.0– 5.6	4.3– 4.9	3.6– 4.2	2.9– 3.5	2.2– 2.8	1.5– 2.1	0.8– 1.4	≤0.7
Intermalleolar distance (cm)	≥120	110– 119.9	100– 109.9	90– 99.9	80– 89.9	70– 79.9	60– 69.9	50– 59.9	40– 49.9	30– 39.9	≤30
Cervical rotation angle (°)	≥85	76.6– 85	68.1– 76.5	59.6– 68	51.1– 59.5	42.6– 51	34.1– 42.5	25.6– 34	17.1– 25.5	8.6– 17	≤8.5
The BASMI score is the mean of the score of the 5 compartments											

Figure 20 Intermalleolar distance.

9.2.3 Evaluation of range of motion in daily practice

Abnormal postures have to be carefully checked in order to provide the best physical therapy. Once the loss of lumbar lordosis has appeared, thoracic kyphosis and a fixed flexed posture of the cervical spine may follow. The most disabling abnormal posture is the loss of the horizontal view, for which a surgical spinal intervention (*vertebral osteotomy*) may need to be considered (*see also above*).

9.2.4 Hip involvement

Hip involvement is closely related to the severity of spinal ossification and is responsible for significant functional impairment. The prevalence after 10 years of disease is around 10–15% in Western European countries, but up to 40–50% in other parts of the world, such as North Africa. It is typically bilateral. The significance of hip involvement has been shown in a recent multinational study, in which 5% of the patients underwent a total hip arthroplasty. The intermalleolar distance of the BASMI reflects the degree of hip involvement.

9.3 Can we predict the further course of the disease?

The disease course of AS is highly variable and one-third of patients with AS will develop a severe disease, accompanied by structural changes such as syndesmophytes and ankylosis in the spine. Information about the future potential severity of the disease is therefore important. Similar to rheumatoid arthritis, there is a trend towards treating patients efficiently as early as possible and before irreversible structural damage has occurred, although the evidence to support this strategy is currently more limited than in rheumatoid arthritis.

Prognostic assessment is important to guide treatment strategies. Candidate predictors for potentially severe disease are shown in box 15. In general, the negative predictive value is more reliable than the positive predictive value. In other words, the absence of any of the variables listed in box 15 is highly predictive of a good prognosis. Recent data from inception cohorts showed that patients with raised CRP, with extensive inflammation in the SI joints, and patients who smoke are at higher risk of developing structural changes in the SI joints than those patients who do not have these factors.

Box 15 Candidate predictors for potentially severe disease

Presence of the following parameters during the first 2 years:

- Hip involvement
- Erythrocyte sedimentation rate >30 mm/hr
- Reduction in lumbar spine movement
- Dactylitis
- Monoarthritis/oligoarthritis
- Age at onset before 16 years
- Diarrhoea
- Urethritis
- Psoriasis
- Inflammatory bowel disease

10 Management of axSpA

ASAS together with EULAR published in 2006 and updated in 2010 the ASAS/EULAR recommendations for the management of AS (Braun et al, 2011*). Since the evidence on the course and management of axSpA is limited and the literature is mainly based on data about AS, it has been decided to restrict the recommendations to AS, although the experts unanimously agreed that these recommendations can equally be applied to patients with axSpA.

The updated management recommendation includes overarching principles which deal with specific modalities important for each patient with AS. Eleven recommendations address several aspects of the management of patients with AS. It has been stated that management requires a multidisciplinary treatment coordinated by the rheumatologists since AS is a potentially severe disease with diverse manifestations as we have shown in the review above. To prevent deteriorating functioning in patients with AS it is important that the optimal management is based on a combination of non-pharmacological and pharmacological treatment modalities (see chapter 12, Treatment) and that the decision about optimal management is based on a shared decision between patients and rheumatologists. Discrepancies between patients' and physicians' perspectives of the disease and its outcome are well known and should be taken into account in the daily routine for

treating patients with AS. In patients with extra-articular manifestations, close working with specialists in gastroenterology, dermatology and ophthalmology is also required.

10.1 Patient education

Patient education is crucial for the successful management of patients with SpA. Once the diagnosis is made, the patient should be given a clear description of the nature of the disease, including an explanation of the potential clinical symptoms, complications and the possible progression of the target symptom.

To clarify this approach:

- The patient has to be educated clearly about the differences between back pain due to SpA and mechanical back pain. The most common misconceptions are that (a) NSAIDs have a higher toxicity than efficacy and (b) physiotherapy has no effect on the long-term outcome of back pain.
- Information about the possible occurrence of spinal ankylosis and abnormal postures may lead to better compliance with proposed treatments, such as NSAIDs and physiotherapy, and will give the patient a better understanding of the benefits and importance of regular follow-up.
- The patient must be informed about the possibility of the occurrence of other clinical symptoms of SpA. For example, the risk of developing acute anterior uveitis, in which case an early ophthalmic review would be required.

Summary points

- SpA is a heterogeneous family of disorders characterised by axial inflammatory pain, peripheral arthritis, dactylitis and enthesitis.
- There may be associated extra-articular features such as inflammatory bowel disease, psoriasis, urethritis and anterior uveitis.
- Patients positive for the HLA-B27 tissue antigen have an increased risk of developing SpA.
- Genetic studies suggest also the existence of other predisposing genes, such as the *IL-23R*, *ERAP1*, *IL-1R2*, *ANTXR2*, *TNFSF15*, *2p15* and *21q22* genes.
- Apart from the genetic factors, environmental factors, particularly infections, predispose to the occurrence, or influence the severity, of the disease.
- The IL-23/-17 axis seems to play important role in the pathophysiology of SpA
- The initial symptom of AS is typically inflammatory lower back pain of insidious onset, becoming persistent after a few months. However, a diagnosis of SpA can be made in the absence of inflammatory back pain.
- Arthritis of the peripheral joints is typically oligoarticular, asymmetrical, with involvement of both small and large joints, predominantly of the lower limbs. Dactylitis is key feature of SpA, particularly PsA.
- Acute anterior uveitis is the most common extra-articular manifestation, with 25–40% of patients experiencing one or more episodes. It requires urgent ophthalmological referral since it can lead to permanent visual loss.
- MRI can detect inflammatory lesions long before definite lesions are visible on plain radiographs. A negative MRI does not exclude a diagnosis of SpA.
- The radiographic hallmarks of AS are sacroiliitis, erosions and sclerosis.
- The new ASAS criteria for axSpA have made it possible to diagnose early non-radiographic axSpA as well as established AS.
- Using the new ASAS criteria, diagnosis of axSpA can be based on clinical grounds. This requires the presence of HLA-B27 plus two other SpA features.
- A core set of tools for assessing disease activity and severity in order to facilitate treatment and record keeping has been proposed. This core set consists of patient-reported outcome measures as well as clinical and radiological measurements.
- The domains of pain, patient global assessment of disease activity, morning stiffness, fatigue, spinal mobility and physical function are included in all core sets.
- NSAIDs and exercise are recommended as first-line therapies in patients with axSpA. For those patients who still have an active disease the introduction of tumour necrosis factor α blockers is a major advance in the management of axSpA.

IN-DEPTH DISCUSSION I

**Classification and diagnosis in early axial
Spondyloarthritis**

Spondyloarthritis (SpA) comprises a group of conditions characterised by sacroiliitis, spondylitis, peripheral arthritis and enthesitis. Over the past years a lot of research has been carried out in this field which has led to major advances and better understanding of the disease pathogenesis. The availability of MRI and the efficacy of TNF- blocking therapies have been the main driving force for these developments. MRI allows for earlier diagnosis while improved biologic therapies may allow for commencement of treatment possibly before structural damage has taken place.

Assessment of SpondyloArthritis International Society (ASAS) classification criteria for axial SpA

The validated classification criteria for axial SpA herald a new era in this field making it possible to diagnose both early axial SpA without radiographic changes as well as established SpA (1, 2). This will facilitate the conduct of clinical trials and observational studies as well as the daily management of axial SpA. The term axial SpA encompasses a disease spectrum ranging from inflammatory symptoms and signs but no radiographic changes through to more established disease with obvious structural changes consistent with ankylosing spondylitis (AS).

Although the modified New York criteria for AS (3) perform well in patients with established disease they do not allow diagnosis of SpA until radiographic changes have occurred. Radiographic changes reflect consequences of the inflammation rather than the inflammation itself. MRI has become an invaluable tool in early diagnosis as it can detect active inflammation in the spine and sacroiliac joints (SIJ) that is not visible on plain radiography. Sacroiliitis can be detected by MRI years before it is apparent on a plain radiograph. The previous concept of “pre-radiographic” sacroiliitis implied would develop radiographic changes over time, but recent data suggests that only a proportion will progress, so the preferred terminology now is “non-radiographic”. It is worth noting that the term “non-radiographic” refers to patients with no current imaging evidence of sacroiliitis and those with MRI but not x-ray evidence of sacroiliitis who fulfil the clinical and imaging arms, respectively, of the ASAS classification criteria for axial SpA. Our current stage of knowledge does not allow us to accurately predict which individuals will develop progressive disease, although male gender and the presence of syndesmophytes generally predict progression at a group level. Early diagnosis is important because it has been shown that the burden of early disease is still substantial and comparable to that of later stages (4). In addition anti-TNF agents have been shown to be effective in early disease (5). There is little evidence at present that anti-TNF agents can stop, retard or reverse radiologic progression, but there is gradually accumulating longer term observational data to suggest this may be the case.

Earlier criteria such as the European Spondyloarthropathy Study Group (ESSG) (6) and the Amor criteria (7) were created before MRI was available. Using these criteria patients without sacroiliitis on plain radiography are said to have undifferentiated SpA, without differentiating between axial- and peripheral SpA. This is

relevant when deciding about treatment particularly the use of TNF-blockers in non-radiographic axial SpA. The modified New York criteria focus on AS as a separate disease rather than as part of an entire SpA spectrum. With the ASAS classification criteria for axial SpA there is a recognition of the concept of axial SpA, with AS representing one potential outcome rather than a separate disease. More importantly it has become possible to diagnose non-radiographic axial SpA, a need which was previously unmet.

The ASAS classification criteria for axial SpA were published in 2009. Initially, draft criteria were created based on review of 71 'paper patients' by 20 international experts (1). These criteria were then validated in a large multicentre study (2). The study population consisted of 649 patients with chronic back pain representing the whole spectrum of SpA from the early non-radiographic stage to radiographic sacroiliitis with a mean duration of symptoms of 6.1 years.

The classification criteria comprise a 10-item list of SpA features. Interestingly no spinal mobility measures were included in the new criteria as in early disease these were not found to be useful to differentiate between axial SpA and no SpA. The axial SpA classification criteria have a sensitivity of 82.9% and a specificity of 84.4% with a positive likelihood ratio of 5.3 for axial SpA, increasing the post-test probability of a diagnosis of axial SpA from 60.2% to 89%. When compared to the ESSG and Amor criteria the new ASAS classification criteria were shown to perform better. These criteria are primarily designed as classification criteria and there are currently no diagnostic criteria for axial SpA, so in daily clinical practice one has to adapt a more flexible approach. There are important differences between classification and diagnostic criteria. Most importantly, classification criteria are designed to be applied where the *a priori* diagnosis of axial SpA is suspected in order to create more homogenous cohorts for research purposes. In contrast, diagnostic criteria are applied in clinical settings where the *a priori* diagnosis is unknown, so also require clinical acumen to exclude other potential causes for the patient's symptoms and findings, which is not part of classification criteria. Therefore, while classification criteria can be useful in clinical practice, they cannot simply be applied using a "check box" approach. Given a rheumatology setting with a prevalence of 60% axial SpA as was present in this study these criteria should perform satisfactorily in clinical practice in this setting. Whether they perform as well in populations with a lower prevalence needs to be investigated.

MRI in early axial SpA

The most significant change in the ASAS criteria is the inclusion of MRI as a defining criterion. Axial disease, unlike peripheral disease, is hindered by lack of specific clinical signs or laboratory features. Reliance on clinical symptoms and radiographic changes has resulted in diagnostic delay which may take up to 10 years from onset of symptoms (8). MRI sensitivity for active early inflammation is now well established. MRI has been shown to predict progression to AS as well as response to anti-TNF blocking treatment both in early and

established diseases (5, 9). MRI is now the imaging modality of choice to visualise the SIJs and spine in early disease and is increasingly used clinically and in research (Figure 1).

Figure 1: Florid unilateral sacroiliitis in a patient with a recent diagnosis of Psoriatic arthritis. Erosions (black arrow) of sacroiliac joint and bone oedema (white arrow) are evident. T2- Turbo Inversion Recovery Magnitude (TIRM) sequence.

Indeed, in the validation of the new criteria, MRI findings of the SIJs led to a change in diagnosis in 21% of cases. However, one has to recognise that MRI has limitations in identifying inflammation. In the new ASAS criteria validation cohort, 35% of patients did not have SIJ inflammation on MRI. A negative MRI scan therefore does not exclude a diagnosis of SpA. The new criteria address this issue and allow a diagnosis of axial SpA based on clinical grounds without the need of a positive MRI. In fact a classifying diagnosis of SpA can be made in the presence of HLA-B27 plus 2 other SpA features without MRI or radiographic evidence. This makes HLA-B27 a critical parameter for the diagnosis of SpA in these patients, although it should be noted that the clinical arm had a lower specificity (86%) compared to the imaging arm (97.5%). The authors report that out of the 130 patients with a diagnosis of axial SpA who had undergone an MRI of both SIJs and spine, only 5.4 % had inflammatory lesions solely in the spine without SIJ involvement. In fact the majority had lesions either in SIJs alone or at both sites. Further study needs to be carried out to see whether including spine MRI with SIJ MRI improves sensitivity and specificity of these criteria. T2-weighted fat suppressed fast spin-echo and STIR sequences are recognised as the imaging of choice for bone marrow oedema (BMO) (10). T2-weighted sequences suppress the fat signal allowing visualisation of the bright inflammatory signal in the bone marrow. STIR sequences are generally sufficient to detect inflammation and the use of contrast medium is not recommended in the EULAR recommendations for imaging in the diagnosis and management of SpA (11).

BMO has been shown to correlate with histological inflammation (12). However BMO can also arise from mechanical stress, insufficiency fractures or malignant tumours, so BMO alone does not necessarily imply a diagnosis of axial SpA. As with all imaging, the results need to be interpreted in the context of the clinical presentation and not in isolation. Few studies have addressed the specificity of MRI. Interpretation and the diagnostic value of MRI vary, depending on the facilities and the level of training. This has created an urgent need for a standard definition of active MRI sacroiliitis to be implemented for research purposes and in clinical practice. Recently the ASAS/OMERACT MRI group consisting of two radiologists and eight rheumatologists with a special interest in SpA has put forward a definition for MRI sacroiliitis after reaching a consensus (13). This states that BMO (on STIR) or osteitis (or T1 post Gadolinium) must be clearly present in subchondral or periarticular BMO with sufficient amount of signal. Sufficient signal is defined as more than one BMO lesion on a single slice or if there is only one BMO lesion, this must be present on two consecutive slices. This definition should be applied for the criterion “active sacroiliitis by MRI” in the new ASAS classification criteria for axial SpA. Further prospective validation of this definition with age- and sex-matched controls and radiographic follow up is still required. Inflammatory lesions based on synovitis, enthesitis or capsulitis, but without BMO, were not included in the definition of sacroiliitis on MRI since these very rarely occur in the absence of BMO. The authors also point out that further studies need to look at defining minimum size and variable grades of severity of BMO. Fatty changes seen on T1 MRI sequences indicate chronic changes which may be the consequence of inflammatory or degenerative processes, so are less specific and are not currently included in the ASAS classification criteria, although they may be of value in clinical practice in patients in whom a high clinical suspicion of axial SpA exists (e.g. a 20 year old man with Crohn’s disease).

In a recent paper (14), low severity BMO has been found in individuals with mechanical back pain. On the other hand grade 2 or 3 severity lesions (based on the Leeds scoring system) were more marked in inflammatory back pain (IBP) patients and linked to HLA-B27. Equally important was the fact that a third of patients showed lesions simultaneously in the SIJ and in the lumbar spine, while a small minority had lumbar spine lesions without SIJ lesions.

Until a few years ago, the SIJs were the main site of interest and little attention was given to the spine. Spine inflammation was mainly used to assess disease activity, as a guide to support initiation of anti-TNF treatment and assessment of treatment efficacy. Lately there has been considerable interest in MRI of the spine, both from the diagnostic and prognostic perspectives. It has been shown that in clinically active axial SpA, the SIJs are normal in up to 20% (15) although other studies have reported lower levels. From the prognostic point of view it would be very useful to identify which inflammatory lesions will progress to syndesmophyte formation, since functional outcome is directly related to spinal disease severity but not to SIJ disease (16). There are several MRI scoring systems for assessment of spinal inflammation, including the Ankylosing spondylitis spine

score for activity (ASspiMRI-a), the Berlin method, and the Spondylitis Research Consortium of Canada (SPARCC), although their current use is largely limited to clinical trials (17-18).

Inflammatory back pain

Another important difference in the new ASAS criteria is that IBP is no longer an obligatory criterion. For entry one must have back pain for at least 3 months starting before 45 years of age, while IBP counts as an extra SpA parameter. New clinical criteria have also been proposed for IBP (19), known as the ASAS 'expert' criteria. In this real patient study, experts were blinded to the patients' diagnosis and the criteria scrutinised for their capacity to differentiate between IBP and non-IBP, rather than for diagnosis of AS versus non-AS as previously performed in the Calin's criteria (20). Statistical analysis was then carried out to distinguish which criteria were independently specific to IBP. The new expert criteria should be applied to patients with chronic back pain for > 3 months and the criteria are fulfilled if at least four out of following five parameters are present: age at onset < 40 years, insidious onset, improvement with exercise, no improvement with rest and pain at night (with improvement upon getting up). These criteria were shown to have a sensitivity of 72.4 % and a specificity of 82.2%. These new criteria compare to the previous 2006 Berlin criteria (21) published by the same group. The main difference is the exclusion of early morning stiffness, as well as pain in the second half of the night. The reason given for not including these parameters was that duration and timing were not specifically analysed in this study. Validation in the primary care setting still has to be carried out.

In 2009 ASAS published a handbook guide for assessment of axial SpA (22). This is a compendium of validated classification and outcome measures including clinical and radiological measures.

Conclusion

These are exciting and challenging times in the SpA field. The new ASAS criteria for axial SpA encompassing the whole disease spectrum of axial SpA are a major breakthrough in facilitating future research and earlier treatment in clinical practice. Availability of MRI is another key advancement making it possible to diagnose non-radiographic SpA. However, it is worth remembering that a significant number of patients with features of SpA have normal MRI scans, which implies that a negative MRI of the SIJ does not exclude SpA. In some cases it is still difficult to make a definite diagnosis and the classification criteria are not designed to be rigidly applied in daily clinical practice, so careful clinical assessment and diagnostic work-up remain key.

IN-DEPTH DISCUSSION II

HLA and the SPONDYLOARTHROPATHIES

Introduction

The association between spondyloarthropathies and HLA antigens (specifically HLA-B27) has been a major scientific advance because it provides an insight into the complex distribution of genetics, environmental factors and immunology to the pathogenesis of this group of diseases.

HLA-B27 occurs in 6-10% of Caucasians but is present in more than 90% of patients with Ankylosing Spondylitis (AS). Some of the other spondyloarthropathies also show an increased frequency of HLA-B27.

The HLA System

Human leucocyte antigens (HLA)

These are also known as the Major Histocompatibility Complex (MHC) and are cell surface glycoproteins which are present on nucleated cells. Their function is not fully understood but they are the cellular markers of individuality and they play an important role in antigen presentation to T cells and immunological reactivity at the cellular level.

There are two main groups of MHC proteins: the class I antigens (HLA-A,B and C) which are found on most nucleated cells, and the class II antigens (HLA-D/DR) which are only found on cells in the immune system involved in antigen presentation.

The class I antigens have two components: a small fragment identified as β 2 microglobulin, and a larger component (the heavy chain) which carries the antigenic specificity. The base of the antigen is embedded within the cell membrane while the remainder projects above the cell surface with the antigenic portion exposed.

Genetics of the HLA System

Each individual has a limited number of antigens on the cell surface giving each person a biological individuality. The area of chromosome 6 that codes for the HLA antigens is also called the MHC. The MHC also contains the genes coding for complement components C2, C4 and factor B. The HLA antigens are genetically determined and can be divided into groups on the basis of the gene locus which codes for them. These loci have been designated A, B, C, and D/DR.

At each locus, a number of different alleles can be found and these code for the antigens of the A, B, C, D/DR series. To date at least 20 different antigens of the A locus, 30 antigens of the B locus, 8 of the C locus, 10 of the D locus and a similar number of DR antigens have been identified.

Unanswered/Partly answered Questions

The shared genetic background partly explains the inter-relationship between the various spondyloarthropathies. However, several observations remain unresolved including:

1. Not all patients with HLA-B27 develop disease while up to 5% of Caucasian AS sufferers are HLA-B27 negative.

HLA-B27 is the primary disease susceptibility gene for AS, and is thought to contribute about 49% of the population-attributable genetic risk of AS for Caucasians [1-2].

Recent research as part of the genome-wide association study (GWAS) approach using single nucleotide polymorphism (SNP) genotyping techniques have identified several non-MHC genes which confer susceptibility to Crohn's disease and psoriasis such as the gene for the interleukin-23 receptor (IL-23R). IL-23 appears to be a key factor in the regulation of the proinflammatory Th17 cells [1-4]. IL-23 is selectively overexpressed in subclinical intestinal inflammation sites in AS at levels similar to those seen in Crohn's sufferers. The IL-23R gene is thought to contribute roughly 9% of the population-attributable genetic risk for AS in Caucasians [1-3].

Another gene, ERAP1 (also called ERAAP or ARTS1) located on chromosome 5 encodes a transmembrane aminopeptidase with various immunologic functions including trimming of peptides for presentation by MHC class I proteins. Another function of ERAP1 and its genetic variants is the cleavage of cell surface receptors for the pro-inflammatory cytokines IL-1, IL-6 and TNF resulting in down regulation of their signal.

ERAP1 is strongly associated with AS and is thought to contribute roughly 23% of the population-attributable genetic risk for AS in Caucasians [1-2]. Interestingly, the association with ERAP1 is only seen in patients who are HLA-B27 positive, representing a true gene-gene interaction. ERAP1 is also associated with a number of other SpA-related conditions, including Crohn's disease and psoriasis. It is also now recognised that while some ERAP1 variants increase the susceptibility to AS, others are protective.

2. The association between AS and HLA-B27 in blacks [5] (40-50%) and Japanese [6] is not as striking as that in Caucasians.

Nearly 60 subtypes of HLA-B27 have been identified. However, epidemiological studies linking their associations with disease are not present for many of the subtypes [7]. The subtypes from B*2702 through to B*2710, B*2714, B*2715, B*2719 and B*2730 all have proven associations with spondyloarthropathies [8]. The HLA-B*2706 and HLA-B*2709 subtypes were until recently thought to be protective but a few cases of AS have been reported suggesting that they are not absolutely protective but weakly associated with the development of AS [9-11].

These epidemiologic associations between HLA-B27 subtypes and disease are important because they may help elucidate the mechanism of HLA-B27's association with the spondyloarthropathies [12].

3. Relatives of probands with both sacroiliitis and HLA-B27, even when carrying an identical HLA haplotype, frequently remain disease free. HLA-B27 positive relatives of HLA-B27 positive patients are about 20 times more likely to develop AS than are HLA-B27 positive relatives of healthy HLA-B27 positive subjects [13].

The difference in clinical phenotype between HLA-B27 positive and HLA-B27-negative patients has been recognised for over 30 years [14; 15]. HLA-B27 negative AS tends to have a later disease onset, lower incidence of acute anterior uveitis and is significantly more frequently associated with psoriasis, ulcerative colitis and Crohn's disease. Familial aggregation is also uncommon [14; 15].

A recent study from Finland confirmed the observation that individuals who are homozygous for HLA-B27 are more than three times as likely to develop AS as those who are heterozygotes [16; 17]. The authors hypothesized that possible increased cell surface expression of HLA-B27 or potentially increased effects from linked genes may influence the occurrence of the disease process.

4. What is the evidence that HLA-B27 may have a pathogenic role in the Spondyloarthropathies?

At present the precise explanation for the association between HLA-B27 and AS is unknown. The current three major theories (shown in Figure 1) proposed to explain how HLA-B27 contributes to AS are:

1. The arthritogenic peptide theory
2. Homodimerisation theory
3. Endoplasmic reticulum stress and unfolded protein response theory

The "arthritogenic peptide" theory suggests that HLA-B27 has the ability to bind a peptide(s) from a microbial source with the consequent generation of an HLA-B27 restricted CD8+ cytotoxic T cell response [18]. Such a peptide would be bound and presented by all the HLA-B27 disease-associated subtypes but not by other HLA Class I molecules. This hypothesis was dealt a blow by studies in the B27 transgenic mouse model for spondyloarthropathies where it appears that CD8+ T cells do not appear to be involved or required for development on the disease in this model.

Various hypotheses have been put forward on the basis of the complicated structure of HLA-B27 which in addition to having specific antigen-presenting sites, also tends to fold and misfold, forming covalent homodimers that can be expressed on the cell surface. These can then be recognized by leucocyte receptors on immune cells, including Th17 and Natural Killer cells, leading to IL-17 production [18-21]. This theory has

gained some traction recently with the demonstration of differences in KIRD3DL2 receptor binding to HLA-B27 subtypes, independent of the sequence of bound peptide [22].

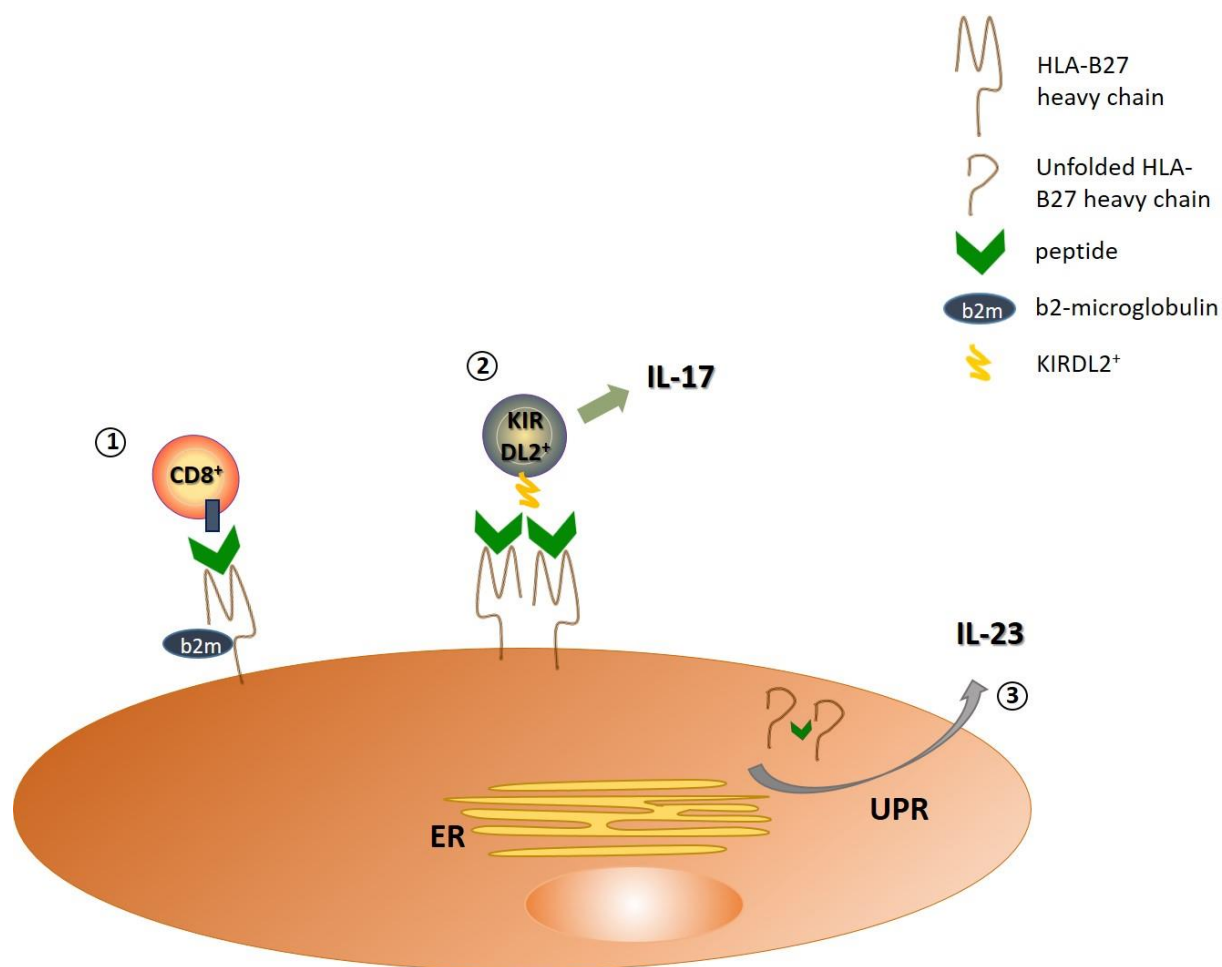

This mechanism however, would not fully explain the differential association of AS with the various subtypes of HLA-B27 described earlier on, with some subtypes appearing to confer a degree of protection (although not complete) to developing the disease.

In addition to forming homodimers, it has been proposed that HLA-B27 may misfold in the endoplasmic reticulum, leading to endoplasmic reticulum stress and the unfolded protein response. Recent data has however failed to demonstrate this in AS and raised doubt about this model.

An older hypothesis proposed molecular mimicry between a viral peptide, such as Epstein-Barr virus, and a self-derived peptide as a potential mechanism. This in turn would trigger a cross-reactive cytotoxic T cell response that activates cell lines that have not been eliminated in the thymus. It is thought that these self-peptide-activated T cells may then contribute to the inflammatory process in later years in AS patients [19-22].

On the balance of the evidence currently available it is unclear whether HLA-B27 predisposes to AS via more than one mechanism or by different mechanisms in different patients. While the exact mechanism of the long recognised association of HLA-B27 with AS remains elusive, the study of HLA-B27 has gained renewed momentum with the identification of other non-HLA susceptibility genes in AS and improved understanding of other components of the immune response in this condition.

Figure 1: HLA-B27 theories. 1. Arthritogenic peptide theory: folded HLA-B27 chain complexed with antigenic peptide and b2 microglobulin activates CD8⁺ T cells. 2. Homodimerisation theory: homodimerized HLA-B27 chains activate KIRDL2⁺ cells to produce IL-17. 3. Unfolded protein response theory: unfolded HLA-B27 chains accumulate in the endoplasmic reticulum, leading to the production of inflammatory cytokines and IL-23. KIR: killer immunoglobulin-like receptor, ER: endoplasmatic reticulum, UPR: unfolded protein response

Management of spondyloarthritis

Anna Moltó, Pascal Claudepierre, Irene van der Horst-Bruinsma

A previous version was co-authored by Irene van der Horst-Bruinsma, Mirjam de Vries, Filip Van den Bosch, Joachim Sieper, Hiltrun Haibel, Herman Mielants and Philippe Carron

LEARNING OUTCOMES

- ➔ Describe and explain the differences between axial and peripheral spondyloarthritis in the management of spondyloarthritis (SpA)
- ➔ Describe and explain the important role of physical therapy, non-steroidal anti-inflammatory drugs and biologic drugs as well as the limited effect of disease-modifying antirheumatic drugs in the management of SpA
- ➔ Make treatment decisions, taking possible extra-articular manifestations, such as uveitis, psoriasis and inflammatory bowel disease, into account
- ➔ Describe the use of biologic agents, their dose, the indication for treatment and their possible side effects
- ➔ Monitor treatments
- ➔ Describe and explain the role played by allied health professionals in the treatment of rheumatoid arthritis

1 Introduction

The spondyloarthritis (SpA) comprise ankylosing spondylitis (AS), reactive arthritis, arthritis/spondylitis associated with psoriasis and arthritis/spondylitis associated with inflammatory bowel disease (IBD). The main link between them is the association with HLA-B27, the same pattern of peripheral joint involvement with an asymmetrical, pauciarticular, arthritis predominantly of the lower limbs, and the possible occurrence of sacroiliitis, spondylitis, enthesitis, dactylitis and uveitis. The leading clinical symptoms for all subsets of SpA are inflammatory back pain and/or asymmetrical arthritis, predominantly of the lower limbs.

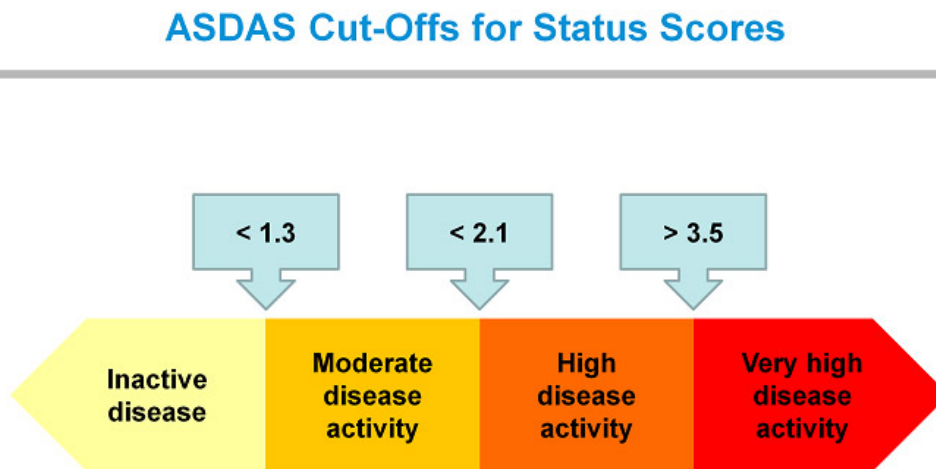

According to the recently published Assessment of SpondyloArthritis international Society (ASAS) classification criteria, SpA can be divided into two subsets: axial and peripheral SpA. The term axial SpA (axSpA) covers both patients with established AS (with radiographic sacroiliitis) and patients without definitive chronic changes visible on X-ray examination, termed non-radiographic axial SpA. When a clinical diagnosis of axSpA has been established, the disease can be classified after the patient has had chronic back pain for longer than 3 months starting at an age <45 years and if there is either sacroiliitis on imaging (which could be chronic changes on X-ray examination or early active inflammatory changes on MRI) plus the presence of one additional typical SpA feature or if the patient is HLA-B27 positive with at least two additional typical SpA features.

Peripheral SpA (pSpA) is characterised by peripheral arthritis, enthesitis or dactylitis. Except in the subgroup of patients with psoriasis, very few studies, and no drug approval, concern pSpA. The term psoriatic arthritis (PsA) comprises different subtypes of inflammatory locomotor manifestations, including arthritis of the fingers or toes joints. There are many drug trials dedicated to this subtype with specific approvals. Therefore, in this article, management for both axSpA and PsA will be covered, and separately. The following discussion of therapeutic options will be split into predominantly axial (including AS) or predominantly peripheral manifestations of SpA (including PsA, IBD arthritis and reactive arthritis).

2 Axial spondyloarthritis

To judge the efficacy of a treatment the Bath AS Disease Activity Index (BASDAI, described in chapter 11) or the ASAS working group response criteria are most often used. Both are based on patients' reported symptoms. More recently, the AS Disease activity Score (ASDAS) was introduced, which encompasses acute phase reactants (C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR)) in addition to patient-reported outcomes from questionnaires (BASDAI: back pain, morning stiffness and patient global assessment of disease activity on a Visual Analogue Scale). Cut-off values for different states of disease activity have been described, with an ASDAS value >2.1 indicative of highly active disease (as described in chapter 11) (figure 1).

ASDAS, Ankylosing Spondylitis Disease Activity Score; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; bDMARD, biological disease-modifying antirheumatic drug; TNFi, tumour necrosis factor inhibitor; IL17-inhibitor, interleukin-17 inhibitor. *Either BASDAI or ASDAS, but the same outcome per patient. (Reproduced from van der Heijde et al, *Ann Rheum Dis* 2017;76: 978-991.)

Recommendations emerging from the ASAS/EULAR group for the management of the whole group of axSpA have recently been updated in 2016, and are part of the EULAR recommendations. These recommendations are summarised in an algorithm (figure 2) and in 13 bullets (figure 3) and will be discussed in more detail. It can be easily seen from this that non-steroidal anti-inflammatory drugs (NSAIDs) and tumour necrosis factor (TNF) blockers are, up to now, regarded as the most important and almost the only relevant form of medical treatment which has to be combined with non-pharmacological treatments during the entire course of the disease.

Figure 3 2016 Update ASAS-EULAR recommendations for the management of axSpA . (Reproduced from van der Heijde et al, *Ann Rheum Dis* 2017;76: 978-991.)

Table 1 2016 Update of the ASAS-EULAR recommendations for the management of axSpA				
Overarching principles		LoE	GoR	LoA (0–10)
1	axSpA is a potentially severe disease with diverse manifestations, usually requiring multidisciplinary management coordinated by the rheumatologist			9.9 (0.31) 100% ≥8
2	The primary goal of treating the patient with axSpA is to maximise health-related quality of life through control of symptoms and inflammation, prevention of progressive structural damage, preservation/normalisation of function and social participation			9.8 (0.47) 100% ≥8
3	The optimal management of patients with axSpA requires a combination of non-pharmacological and pharmacological treatment modalities			9.8 (0.45) 100% ≥8
4	Treatment of axSpA should aim at the best care and must be based on a shared decision between the patient and the rheumatologist			9.5 (0.91) 100% ≥8
5	axSpA incurs high individual, medical and societal costs, all of which should be considered in its management by the treating rheumatologist			9.3 (1.17) 97% ≥8
Recommendations				
1	The treatment of patients with axSpA should be individualised according to the current signs and symptoms of the disease (axial, peripheral, extra-articular manifestations) and the patient characteristics including comorbidities and psychosocial factors	5	D	9.7 (0.65) 100% ≥8
2	Disease monitoring of patients with axSpA should include patient-reported outcomes, clinical findings, laboratory tests and imaging, all with the appropriate instruments and relevant to the clinical presentation. The frequency of monitoring should be decided on an individual basis depending on symptoms, severity and treatment	5	D	9.6 (0.78) 100% ≥8
3	Treatment should be guided according to a predefined treatment target	5	D	8.9 (1.45) 93% ≥8
4	Patients should be educated* about axSpA and encouraged to exercise* on a regular basis and stop smoking‡; physical therapy† should be considered	2* 5‡ 1a†	B* D‡ A†	9.6 (0.78) 100% ≥8
5	Patients suffering from pain and stiffness should use an NSAID as first-line drug treatment up to the maximum dose, taking risks and benefits into account. For patients who respond well to NSAIDs continuous use is preferred if symptomatic otherwise	1a	A	9.4 (0.94) 100% ≥8
6	Analgesics, such as paracetamol and opioid-(like) drugs, might be considered for residual pain after previously recommended treatments have failed, are contraindicated, and/or poorly tolerated	5	D	8.8 (0.94) 100% ≥8
7	Glucocorticoid injections* directed to the local site of musculoskeletal inflammation may be considered. Patients with axial disease should not receive long-term treatment with systemic glucocorticoids‡	2* 5‡	B* D‡	9.4 (0.78) 100% ≥8
8	Patients with purely axial disease should normally not be treated with csDMARDs§; sulfasalazine† may be considered in patients with peripheral arthritis	1a†	A	9.2 (0.78) 100% ≥8
9	bDMARDs should be considered in patients with persistently high disease activity despite conventional treatments (figure 1); current practice is to start with TNFi therapy	1a (TNFi); 1b (IL-17i)	A	9.6 (1.09) 93% ≥8
10	If TNFi therapy fails, switching to another TNFi* or IL-17i** therapy should be considered	2* 1b**	B* A**	9.6 (0.95) 97% ≥8
11	If a patient is in sustained remission, tapering of a bDMARD can be considered	2	B	9.1 (1.57) 97% ≥8
12	Total hip arthroplasty should be considered in patients with refractory pain or disability and radiographic evidence of structural damage, independent of age; spinal corrective osteotomy in specialised centres may be considered in patients with severe disabling deformity	4	C	9.4 (0.82) 100% ≥8
13	If a significant change in the course of the disease occurs, causes other than inflammation, such as a spinal fracture, should be considered and appropriate evaluation, including imaging, should be performed	5	D	9.9 (0.31) 97% ≥8

§1a (sulfasalazine; methotrexate); 1b (leflunomide); 4 other csDMARDs.

axSpA, axial spondyloarthritis; bDMARD, biological disease-modifying antirheumatic drug; csDMARD, conventional synthetic disease-modifying antirheumatic drug; GoR, grade of recommendation; IL-17i, interleukin-17 inhibitor; LoA, level of agreement; LoE, level of evidence; NSAIDs, non-steroidal anti-inflammatory drugs; TNFi, tumour necrosis factor inhibitor.

For the management of axSpA, an early diagnosis is important for several reasons: (i) an early correct diagnosis avoids unnecessary diagnostic procedures and wrong treatments; (ii) emphasises the importance of starting

physical treatment early; (iii) enables treatment with NSAIDs to be started and continued in symptomatic patients once the diagnosis is made; (iv) enables early use of TNF blockers in patients with axSpA refractory to conventional treatment in the presence of an active disease and radiographic sacroiliitis and/or inflammation of the sacroiliac joints and/or elevated C-reactive protein (CRP) level; (v) enables the use of another biologic drug, an anti-IL17 one, secukinumab, in case of TNF blockers failure and in presence of radiographic sacroiliitis. A major obstacle in axSpA to any earlier treatment is the long delay of 5–10 years between the first (chronic) symptoms of the disease and the final diagnosis. Thus, starting treatment of axSpA earlier is closely related to the strategies for early diagnosis of axSpA.

2.1 Physical therapy and stop smoking

Physical therapy is the most important non-pharmacological aspect of axSpA management. Its primary aims are to prevent and/or retard restriction of spinal mobility and the development of disability, and to improve the symptoms of pain and stiffness. The effectiveness of these treatments is described in several studies (Van Tubergen et al, 2001) and highlighted in a recent systematic review (van den Berg R, et al 2012) Once the diagnosis is made the patient should be referred to a physical therapist, who will teach the patient the exercises that should be performed regularly.

Because the main long-term outcome, which should be prevented is a flexion deformity of the spine, exercises concentrate on extension and rotation of the spine. Moreover, physical exercises improve muscle strength and decrease the risk of cardiovascular disease.

The patients should be advised to exercise daily at home and to attend weekly group physical therapy. The patient's own efforts are the key to future success and the patient with AS has to be convinced that a daily exercise programme should be a normal part of the day. If patients are symptomatic and complain about pain or stiffness they should be treated, in addition, with NSAIDs or other effective drugs to permit full mobilisation during the exercises.

These exercises should be continued regularly throughout life, particularly in the forms with radiographic signs of ossification or persistent disease activity. Furthermore, patients should be encouraged to participate in activities such as swimming and cycling.

In addition to stimulate physical activity, more evidence has been raised about the negative effects of smoking. Smoking is associated with a more rapid radiographic progression and increases the cardiovascular risk. Therefore, rheumatologists should encourage the Ax Spa patients to stop smoking (bullet 4).

2.2 Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are regarded as the cornerstone of pharmacological intervention for axSpA, reducing pain and stiffness rapidly after 48–72 h. One of the first NSAIDs used for the treatment of axSpA was phenylbutazone, but this drug is seldom used nowadays because of its potential side effects, such as bone marrow depression. Many other NSAIDs have been shown to be effective.

Several placebo-controlled trials investigating different NSAIDs, including cyclo-oxygenase-2 (Cox-2)-selective inhibitors, convincingly showed good efficacy compared with placebo treatment. The advantage of selective Cox-2 inhibitors (celecoxib, etoricoxib) is the lower risk of gastrointestinal side effects such as the onset of peptic ulcers.

A selection of NSAIDs with the maximal recommended daily dose, is shown in table 1. Most importantly, when patients with axSpA are asked about the level of efficacy of NSAIDs, 70–80% report a good or very good improvement of their symptoms. In contrast, this level of response is only reported by about 15% of patients with chronic low back pain of non-inflammatory causes. Furthermore, a good response to NSAID treatment is also used in diagnosis to differentiate chronic back pain in patients with axSpA from pain with other causes (figure 4).

Table 1 Doses of non-steroidal anti-inflammatory drugs used/tested in ankylosing spondylitis

Drug	Half-life (h)	Approved maximal daily dose for arthritis (mg)
Aceclofenac	4–4.3	200
Celecoxib	8–12	400
Etoricoxib	About 22	90
Ibuprofen	1.8–3.5	2400
Indometacin*	2	150
Diclofenac*	About 2	150
Ketoprofen	1.5–2.5	200
Naproxen	10–18	1000
Meloxicam	About 20	15
Piroxicam	30–60	20
Phenylbutazone	50–100	600
Flurbiprofen*	2.8 -12 hours	50, 100 and 200 mg

*Retard formula available.

Normally an optimal effect of an NSAID is reached in about 2 weeks, but sometimes longer is needed to determine the optimal drug and dose. In many patients a full dose is necessary to cover the entire day (table 1). If morning stiffness and pain at night are the predominant symptoms a long-acting night-time dose might be effective.

The high efficacy of NSAIDs for the treatment of axSpA is especially interesting because other anti-inflammatory treatments, such as glucocorticoids or disease-modifying antirheumatic drugs (DMARDs), are

much less effective (see below) than NSAIDs, in contrast, for example, to their good efficacy in the treatment of rheumatoid arthritis (RA).

Figure 4 Efficacy of non-steroidal anti-inflammatory drugs for treatment of ankylosing spondylitis (AS).
(Adapted from 1 Amor et al, *Rev Rheum Engl Ed* 1995;62:10–5; 2 van der Heijde et al, *Arthritis Rheum* 2005a;52:1205–15*.)

Efficacy of NSAIDs for the Treatment of Patients with Ankylosing Spondylitis

1. Amor B et al, *Rev Rheum Engl Ed* 1995;62:10–5

2. van der Heijde D et al *Arthritis Rheum* 2005;52:1205–15

A few studies (figure 5) suggest that NSAIDs might have disease-modifying properties because radiological progression of the spine is retarded when the drugs are given continuously as a daily dose over 2 years compared with an on-demand treatment schedule in radiographic forms of axSpA (i.e. AS). Recently, these data were reanalysed, showing that, in particular, patients with a high inflammatory burden (as measured by time-averaged CRP) benefit from the use of continuous NSAIDs, potentially identifying a subgroup of patients with AS with a favourable risk–benefit ratio. Data from the German Spondyloarthritis Inception cohort (GESPIC) confirmed these findings, showing a slower rate of radiographic progression over 2 years in patients taking high-dose NSAIDs, especially when CRP levels and baseline syndesmophytes are high. Data were based on the ASAS-NSAID intake score (which includes dose and duration of intake). An ASAS-NSAID intake score >50 was associated with a significantly lower radiographic progression based on the modified Stoke Ankylosing Spondylitis Spinal Score (mSASSS) compared with a low NSAID intake (NSAID index <50) (Poddubnyy et al, 2012). However, a recent randomized study comparing continuous use of diclofenac versus on-demand use over 2 years, did not show any favourable spinal structural effect of the continuous regimen, arguing against a

protective structural effect of NSAIDs (or at least diclofenac). Thus it can be considered that the on-demand NSAIDs use, strictly adapted to the symptoms, remains the rule.

Figure 5 Less radiographic progression (mSASSS) after 2 years of continuous versus on-demand use of non-steroidal anti-inflammatory drugs (NSAIDs) (scored with known sequence). mSASSS, modified Stoke Ankylosing Spondylitis Spinal Score. (Adapted from Wanders et al, Arthritis Rheum 2005;52:1756–65*.)

NSAID Therapy in Ankylosing Spondylitis: Radiographic Progression

Thus, the primary aim for the use of NSAIDs, based on their good efficacy for the treatment of signs and symptoms, their ability to facilitate regular physical therapy and their possible influence on radiological progression, is to obtain a patient free of symptoms. Obviously, the side effects of NSAIDs have to be taken into account using such a treatment strategy. The side effects of the non-selective and the Cox-2 selective NSAIDs are now known better than previously. Gastrointestinal side effects, such as peptic ulcers, can be prevented by concomitant use of proton pump inhibitors (such as omeprazole) and the intake of NSAIDs during meals. Selective Cox-2 inhibitors can further reduce the risk of gastrointestinal side effects compared with conventional NSAIDs. An increased risk of cardiovascular event has been reported in studies. A metaanalysis on this issue has shown that COX-2–selective inhibitors were associated with a significantly increased relative risk (1.42 (95% confidence interval [95% CI] 1.13–1.78) ($P = 0.003$) for serious cardiovascular events in comparison with placebo. Ibuprofen and diclofenac showed similar relative risks; however, naproxen was the only NSAID with no increased relative risk that can probably be explained by the capacity of naproxen to inhibit platelet aggregation. Therefore, all NSAIDs, with the probable exception of naproxen, are associated with a slightly increased risk of cardiovascular disease. Patients who still have active disease despite treatment with NSAIDs or who do not tolerate such a treatment should be considered as candidates for other treatments (see below).

A similar efficacy can be expected in the treatment of non-radiographic axial SpA, although there are no studies in this area.

2.3 Analgesics

Simple analgesics have a limited role in the treatment of axSpA. Although there are no formal studies proving their efficacy, analgesics, such as paracetamol and opioids, might be considered for pain control in patients with axSpA in whom NSAIDs are insufficient, contraindicated and/or poorly tolerated (figure 3). Up to one-third of patients take these types of analgesics, often as over-the-counter drugs rather than as prescribed drugs.

2.4 Glucocorticoids

2.4.1 Systemic glucocorticoids

In contrast to their use for the treatment of other inflammatory rheumatic diseases such as RA or systemic lupus erythematosus, systemic glucocorticoids do not play a major part in the treatment of axSpA. This conclusion is based on clinical experience and on one recent clinical trial. While peripheral arthritis often improves if patients are treated with a moderate dose of prednisolone (20–30 mg/day), axial manifestations improve only slightly, if at all, even if a relatively high dose of ≥ 50 mg/day of prednisolone is given.

A few small studies describe good short-term efficacy of intravenous pulse methylprednisolone (1000 mg/day for 3 days) in patients with treatment-refractory AS. However, there is no evidence for a long-term effect of such treatment.

2.4.2 Intra-articular glucocorticoids

Local glucocorticoid injections are recommended for peripheral joint manifestations and are sometimes used for the treatment of enthesitis.

Results for the efficacy of intra-articular injections of glucocorticoids into the sacroiliac joints are contradictory. Usually, 40 mg of triamcinolone is injected. The response rate is probably higher if the intra-articular position of the needle is guided by ultrasound, CT, or—if available—by an open low-field MR scanner. An improvement of symptoms and a reduction of inflammation as detected by MRI have been demonstrated up to 6 months and sometimes even longer. Non-CT- or non-MRI-guided local injections of the sacroiliac joint (most of them probably periarticular) have also been reported to be occasionally effective, although no formal study is available.

2.5 Conventional synthetic disease-modifying antirheumatic drugs (csDMARDs)

In general, csDMARDs, which play such a dominant role in the treatment of RA, have no proven efficacy for the axial manifestations of axSpA.

Sulfasalazine (SSZ) is the best investigated csDMARD for the treatment of axSpA. A Cochrane review article analysed the studies in AS (Chen and Liu, 2005). Eleven studies were included in the data analysis. The pooled analysis showed that the difference between intervention groups was significant, favouring sulfasalazine over placebo, but only when the erythrocyte sedimentation rate and morning stiffness were increased, and not for any other variables. Only one trial investigating patients with a relatively short disease duration (<6 years) showed a benefit in primary outcome parameters, including back pain, spinal mobility and a patient's well-being.

However, several trials showed a higher efficacy of SSZ compared with placebo in the presence of peripheral arthritis. Normally, treatment with a dose of 2×1000 mg/day, which can be increased to 3×1000 mg/day, for a duration of up to 4 months is necessary before a treatment failure can be stated.

SSZ is the only csDMARD that has been tested in a placebo-controlled study in patients with inflammatory back pain as part of a diagnosis of axSpA (without, however, evidence of spinal ankylosis); all 230 patients had a disease duration of <5 years. SSZ was effective for axial symptoms in the subgroup of patients without peripheral arthritis (Amor et al, 1984). However, in the total group, treatment with SSZ (2 g/ day) for 24 weeks was no better than placebo for its effect on signs and symptoms as measured by the BASDAI. In a double-blind, head-to-head comparison of SSZ and etanercept, SSZ effectively reduced peripheral arthritis, but also decreased axial symptoms, as illustrated by a decrease of the ASAS 20 (Braun et al, 2011) but with a smaller treatment effect, compared to etanercept (figure 6).

In view of all these results, SSZ is not recommended for the treatment of axial manifestations of axSpA but can be used in cases of peripheral arthritis in patients with axSpA (figure 3).

Figure 6 Double-blind, head-to-head comparison of sulfasalazine and etanercept. ASAS, Assessment in Ankylosing Spondylitis. (Reproduced with permission from Braun et al, *Arthritis Rheum* 2011;63:1543–51*.)

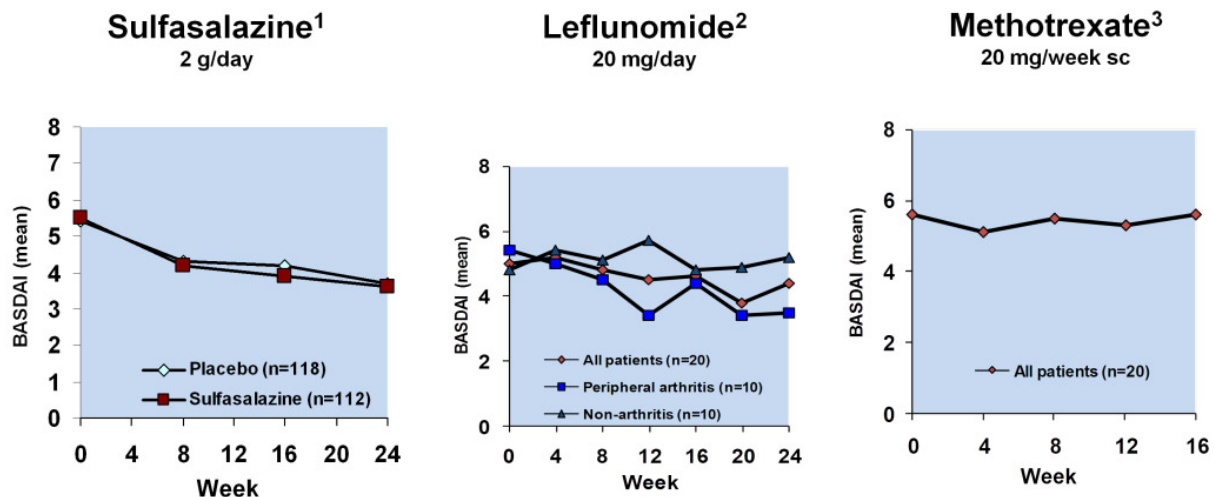

Given the good efficacy of methotrexate for the treatment of RA, the lack of good studies in axSpA is surprising. A recent Cochrane review of the use of methotrexate in AS identified three randomised controlled trials which included 116 participants (Chen et al, 2013). The authors concluded that there is insufficient evidence to support any benefit of methotrexate in the treatment of AS. A 16-week open-label trial of methotrexate, 20 mg subcutaneously a week, showed no effect on axial symptoms and only some improvement in peripheral symptoms. Therefore, methotrexate is not recommended for treatment of the axial manifestations of AS, though in some patients with predominantly peripheral arthritis a trial might be justified.

There is no evidence that any of the other csDMARDs often used for the treatment of RA have a role in the treatment of patients with axSpA (figure 7).

Figure 7 Conventional disease-modifying antirheumatic drugs (CSDMARDs) are largely not effective for the treatment of ankylosing spondylitis. BASDAI, Bath Ankylosing Spondylitis Disease Activity Index. (Adapted from 1Braun et al, Ann Rheum Dis 2006b;65:1147–53; 2Haibel et al, Ann Rheum Dis 2005a;64:124–6; 3Haibel et al, Ann Rheum Dis 2007;66:419–21.)

Conventional DMARDs Are Largely Not Effective for the Treatment of Patients with AS

1. Braun J et al. Ann Rheum Dis 2006;65:1147-53
2. Haibel H et al. Ann Rheum Dis 2005;64:124-6.
3. Haibel H et al. Ann Rheum Dis. 2007;66:419-21.

Leflunomide was tested in AS in an open-label study, which showed efficacy for the peripheral arthritis but not for the axial symptoms. This observation was confirmed by a randomised placebo-controlled trial, which showed no beneficial effects of leflunomide on the axial component of AS (van Denderen et al, 2005*).

There is also no evidence that drugs such as methotrexate, leflunomide or ciclosporin are effective in non-radiographic axSpA.

Thalidomide has also been tested for the treatment of patients with AS in open uncontrolled trials with some success, but is regarded as too toxic for widespread use. It was shown to reduce recurrence of symptoms in patients with AS after discontinuation of etanercept (Brebant et al, 1999; Deng et al, 2013).

Bisphosphonates, have been tested in rheumatic diseases because of their possible anti-inflammatory action and inhibiting effect on osteoclasts. In a 6-month randomised controlled trial 60 mg of pamidronate given intravenously once a month was better than a small placebo-like dose of 10 mg pamidronate, leading to a significant improvement of function and pain. Such an effect only became evident after 3 months of

treatment. A positive effect was not found in other open trials treating patients with AS with the same dosage over 3 months. Therefore, further studies are needed before this treatment can be recommended.

2.6 Biologic disease-modifying antirheumatic drugs (bDMARDs)

Until very recently, TNF blockers were the only available bDMARDs for patients with active axSpA, and were a major breakthrough in the treatment of this disease. Very recently other bDMARDs (i.e., IL-17 inhibitors) have been approved for the use in AS, and have proven a good to very good efficacy in these patients.

2.6.1 TNF α blocking agents

As a consequence of the limited treatment options for patients with AS discussed above, the demonstration of the good or very good efficacy of TNF blockers for patients with active axSpA can be regarded as a major breakthrough in the treatment of this disease. These drugs improve signs and symptoms rapidly and in a high percentage of patients both in patients with AS (figure 8) and nr-axSpA (figure 9), and also reduce acute inflammation in sacroiliac joints and the spine as shown by MRI. However, it should be emphasized that the beneficial effect in nr-axSpA appeared mainly in patients with objective signs of inflammation (elevated CRP and/or active sacroiliitis on MRI, figure 9)). There are some data that support the claim that these treatments also have structure-modifying effects in patients with axSpA, especially if started relatively early in the disease (< 10 years of symptom duration) and after continuation of 4 years or longer (figure 10, Haroon et al, 2013; Machado, 2013; Baraliakos et al, 2014)..

Anti-TNF Therapy Might Slow Radiographic Progression in AS: Data from an Observational Study

Five biological agents targeting TNF are now available, which have been shown to be effective for the treatment of AS and nr-axSpA. These are the chimeric (one-quarter murine and three-quarters human) monoclonal IgG1 antibody, infliximab; the recombinant 75 kDa TNF receptor IgG1 fusion protein, etanercept, two fully human monoclonal antibodies, adalimumab and golimumab and the Fab' fragment of a human monoclonal antibody, certolizumab. All of them have all been approved for AS both in the European Community and the USA. They (except infliximab) have also been approved more recently for patients with nr-axSpA, but only when objective signs of inflammation (elevated CRP and/or MRI sacroiliitis) are present.

Infliximab is given as an intravenous infusion over 2 h in a dose of 5 mg/kg every 6 weeks, etanercept is given subcutaneously at a dose of 50 mg once a week, adalimumab at a dose of 40 mg subcutaneously every other week, golimumab at a monthly dose of 50 mg subcutaneously, and certolizumab at a loading dose of 400mg subcutaneously every other week for one month and then 200mg every other week. (Braun et al, 2012).

In nearly all AS studies infliximab was given intravenously at a dose of 5 mg/kg body weight at weeks 0, 2, 6 and thereafter every 6–8 weeks. In several open-label studies an often dramatic improvement in signs and symptoms was seen beginning on the same day or in the days after the first infusion, which could subsequently be confirmed in placebo-controlled randomised controlled trials (figure 8). In all these studies infliximab was given as monotherapy to patients whose disease was active despite previous treatment with

NSAIDs. Normally, continuation of NSAID treatment was permitted. The crucial end point in all these studies was a 50% improvement in disease activity (BASDAI) or in a composite clinical score (ASAS percentage improvement). This end point was reached uniformly by about 50% of patients in the placebo-controlled trials with about $\leq 10\%$ of the placebo group reaching this level of response, and in up to 60–70% in the open-label studies. Interestingly, between 20% and 25% of these patients with active AS even fulfilled the criteria for partial remission. Also the number of enthesitic sites, the number of affected peripheral joints, function and spinal mobility improved, sometimes significantly, during the placebo-controlled phase. Long-term follow-up results from these studies have been published for up to 8 years, showing a good long-term efficacy, if treatment is continued. After 3 years about 70% of the first patients are still being treated with this drug.

However, when infliximab was stopped after 3 years of treatment, patients relapsed between weeks 7 and 45, and by week 52 all except one patient out of 41 (97.6%) had experienced a flare. When treatment with infliximab was restarted all patients except one improved, similarly to the initial response, and the drug was well tolerated. Thus, for this group of patients with active longstanding disease (mean disease duration >10 years) infliximab has to be given long term. It is not known whether remission or significant improvement can be achieved even after discontinuation of infliximab treatment if patients are treated early in the course of their disease (see also below).

Infliximab has been tested in all placebo-controlled trials in a dose of 5 mg/kg body weight given at weeks 0, 2, 6 and afterwards every 6 or 8 weeks. No study comparing the two intervals has been performed. For some patients the 8-week interval will be sufficient but others need a shorter interval. In general, the interval can be determined according to the patient's symptoms and some patients tolerate even longer intervals. Some data indicate that 3 mg/kg body weight might also be effective in some patients with axSpA.

Over recent years, MRI has proved useful for the detection of acute inflammation in the sacroiliac joints and spine. Serial MRI studies performed in patients in 18 randomized controlled trials showed a significant regression after 3–6 months of treatment of active inflammatory lesions in the spine but not in the placebo-treated group (figures 12).

Several double-blind placebo-controlled trials with etanercept in AS showed a similar efficacy profile to that shown with infliximab, for all the variables discussed above (figure 9): short-term and long-term efficacy (figure 10) and reduction of acute inflammation as shown by MRI (figure 13). In the first studies, etanercept was given in a dose of 25 mg subcutaneously twice a week, but more recent studies showed that 50 mg subcutaneously given once a week has similar efficacy.

MRI of the Sacroiliac Joints Before and After Etanercept Treatment (STIR)

Rudwaleit M et al. Ann Rheum Dis 2005;64:1305-1310 (with permission)

As with infliximab, a relapse occurred at a mean of 6.2 ± 3 weeks, and at 35 weeks all 30 patients had relapsed, when treatment with etanercept was stopped. Again, a comparable clinical response was seen when the drug was restarted.

Adalimumab is another TNF-blocking agent, which has been shown to be effective for the treatment of AS in 2 large randomized placebo-controlled studies (figures 9 and 10). In contrast to other TNF-blocker studies, inclusion of patients with total spinal ankylosis, according to the treating doctor, was permitted. From this small group, three of the six (50%) adalimumab-treated patients achieved an ASAS 20 response at week 12, compared with 0% (none of five) of the placebo-treated patients, indicating that even in longstanding disease there can still be ongoing inflammation and that a proportion of these patients show a good clinical response if treated with TNF blockers.

Golimumab and Certolizumab are the latest TNF-blocking agents to be approved for treatment of AS. It has shown similar efficacy to the other three TNF blockers (Inman et al, 2008; Landewé et al, 2014).

Table 2 Dose and treatment interval for the four TNF-blocking agents used in Spondyloarthritis

Drug	Dosage AS	Dosage PsA	Dosage IBD	Application
Infliximab	5 mg/kg	5 mg/kg	5 mg/kg	IV at weeks 0, 2, 6, q6/q8*
Etanercept	25 mg	25 mg	Not used	SC twice weekly
	50 mg	50 mg		SC once weekly
Adalimumab	40 mg	40 mg	40 mg	SC every 2 weeks†
Golimumab	50 mg	50 mg		SC once monthly
Certolizumab pegol	400mg as load dose and 200mg thereafter	400mg as load dose and 200mg thereafter	400mg	SC every 2 weeks§

*Psoriatic arthritis and IBD; dose escalation to 7.5 mg/kg is possible. †For IBD and plaque psoriasis: initially higher dose. § For IBD 400mg is every 4 weeks

AS, ankylosing spondylitis; IBD, inflammatory bowel disease; IV, intravenously; PsA, psoriatic arthritis; SC, subcutaneously; TNF, tumour necrosis factor.

As in AS, TNF blockers efficacy in nr-axSpA has been confirmed in several randomized clinical trials (figure 9). The first of them concerned adalimumab (Sieper et al, 2013): a trial in which 185 patients fulfilling the ASAS criteria for axSpa but not the mNY criteria for AS were treated either with placebo or 40 mg adalimumab given every second week subcutaneously over 12 weeks. Significantly more patients in the adalimumab group achieved ASAS40 at week 12 compared with patients in the placebo group (36% vs 15%, $p < 0.001$). Shorter disease duration, younger age, elevated baseline C-reactive protein or higher SPARCC MRI sacroiliac joint scores were associated with better week 12 responses to adalimumab.

For inclusion in the infliximab trial, patients with axial SpA with a symptom duration of ≤ 3 years had to be HLA-B27 positive and had to have a positive MRI showing active inflammation in the sacroiliac joint. In this trial with mainly nr-axSpA patients, but also some AS patients, ASAS 40 and ASAS partial remission was reached after 16 weeks of infliximab treatment in 61% and 55% of patients, respectively, compared with a placebo response of 19% and 10%, respectively. Active inflammation of the sacroiliac joints and the spine as shown by MRI improved also significantly more in the infliximab group than in the placebo group.

In the etanercept trial, 215 patients fulfilling the ASAS criteria for axSpA but not the modified New York radiographic criteria for ankylosing spondylitis (as assessed by a radiologist at the central trial site) and with a symptom duration of >3 months but <5 years and an active (score of ≥ 4 on the BASDAI) and refractory disease (unsuccessfully treated with ≥ 2 NSAIDs) were included to receive either etanercept 50 mg/week or placebo and continued background NSAID treatment for 12 weeks. Among them, 174 (81%) had MRI-confirmed sacroiliitis. At 12 weeks, the proportion of patients with improvement according to the ASAS40 was significantly higher in the etanercept group than in the placebo group (32% vs. 16%) and the reduction in MRI-based scores for sacroiliac joint inflammation and spinal inflammation was greater in the etanercept group. Furthermore, post hoc analyses suggested a possible association between higher baseline C-reactive protein levels or MRI sacroiliac joint inflammation scores and higher rates of ASAS40 response to etanercept.

The certolizumab trial included 325 axSpA patients (including both AS and nr-axSpA) who were randomized 1:1:1 to placebo, CZP 200 mg every 2 weeks or CZP 400 mg every 4 weeks (Q4W). Similar improvements were reported with CZP versus placebo in both AS and nr-axSpA subpopulations, with an ASAS 40 response of 56% (Figure 9).

Finally, in the golimumab trial, 198 patients with nr-axSpA according to the ASAS criteria and <5 years of disease were randomized to receive either golimumab or placebo. An ASAS40 response was also achieved by significantly more patients in the golimumab group compared with the placebo group (57% versus 23%).

Taken together, these data indicate that patients with radiographic-axSpA who do not respond to NSAIDs and physical therapy, and with an elevated CRP and/or inflammatory signs of the sacroiliac joints at MRI, respond well to TNF blockers.

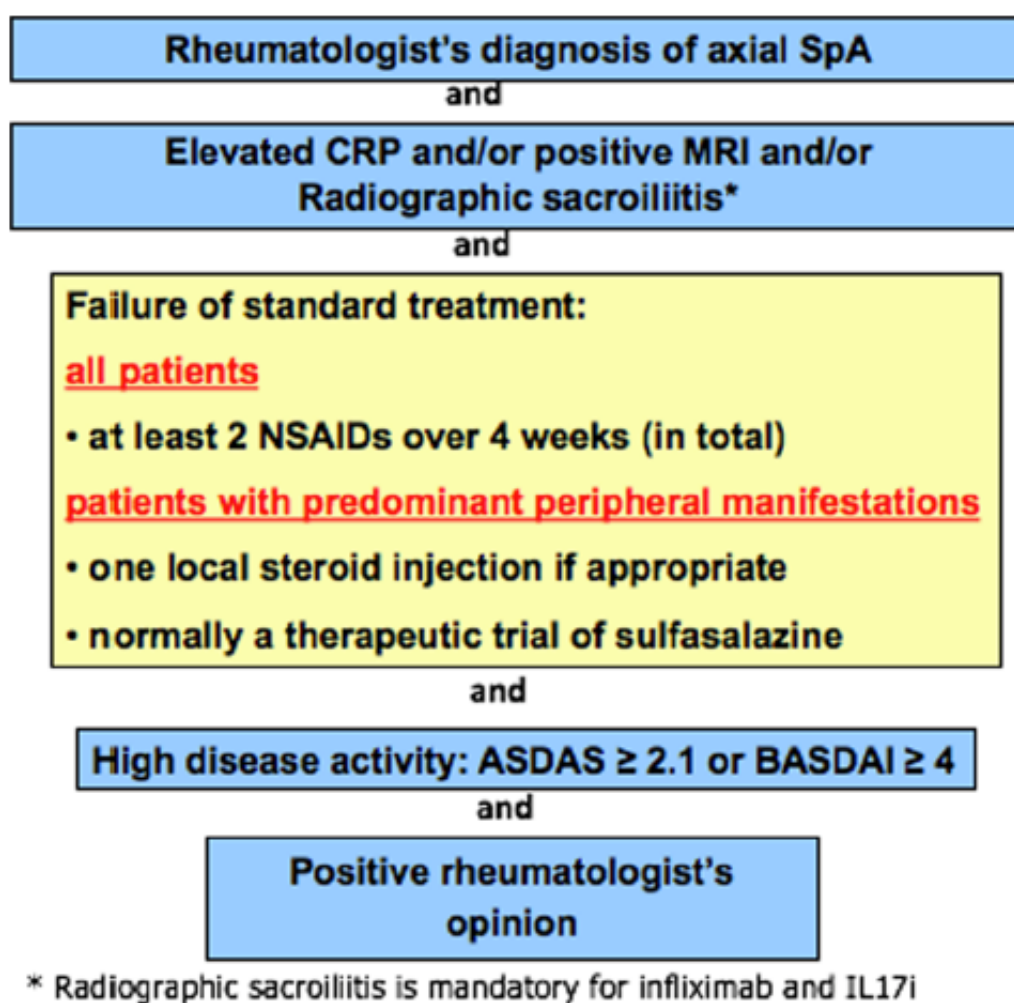

2.6.1.b Anti-TNF therapy in the treatment of juvenile SpA

The first symptoms of AS occur before the age of 20 years in 15–20% of cases, and juvenile and adult SpA should be seen as one disease with a continuum. While the juvenile forms normally present first with a predominance of peripheral manifestations (enthesitis and peripheral arthritis), later on many of them develop typical AS. In two small open-label studies both infliximab and etanercept showed a good efficacy in patients with juvenile SpA or enthesitis-related arthritis (Homeff and Burgos-Vargas, 2002).

2.6.1.c Which patients with axSpA should be treated with TNF blockers?

Recommendations for which patients with axSpA should be treated with TNF blockers are desirable, especially in view of possible side effects and the relatively high costs of these drugs. Thus, patients with the best risk/benefit ratio should be treated preferentially. An international ASAS-EULAR consensus statement for the use of anti-TNF agents in patients with axSpA was recently updated in 2016 (figure 13)..

Figure 13 ASAS-EULAR recommendations for the treatment of patients with axSpA with bDMARDs. CRP, C-reactive protein; MRI, magnetic resonance imaging; NSAIDs, non-steroidal anti-inflammatory drugs; ASDAS, Ankylosing Spondylitis Disease Activity Score; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; IL17i, interleukin-17 inhibitor. (Reproduced from van der Heijde et al, *Ann Rheum Dis* 2011;70:905–8.)

These recommendations were developed on the basis of a review of published reports and consensus meetings of international experts from the ASAS working group. According to these recommendations, for the initiation of bDMARD therapy the criteria shown in figure 13 should be fulfilled.

In the initial recommendations a diagnosis of definitive AS, normally fulfilling the modified New York criteria, was required. However, it should be kept in mind that these criteria were developed as classification criteria

and that patients might not show radiological sacroiliitis but might show, acute sacroiliitis reflected by bone marrow oedema visible on MRI. More recently, ASAS has used the new classification criteria for axial SpA in an update of the ASAS recommendations for the treatment of axSpA with TNF blockers. The presence of active disease for at least 4 weeks as defined by both a sustained BASDAI of at least 4 (on a scale between 0 and 10) or an ASDAS of at least 2.1 and an expert opinion based on clinical features, acute phase reactants and sacroiliitis on imaging modalities is required.

TNF blockers (except infliximab) are now registered in some European countries for the treatment of nr-axSpA but only in cases where CRP is raised and/or sacroiliitis is visible on MRI. The expert will normally be a rheumatologist who will judge, in addition to the patient's symptoms, the objective parameters of activity/inflammation. An additional criterion is the presence of refractory disease defined by the failure of at least two NSAIDs during a 3-month period (this was changed to a 1-month period in the updated version), failure of intra-articular steroids if indicated and failure of SSZ (or methotrexate, according to the updated versions) in patients with peripheral arthritis. These recommendations are also in accordance with the ASAS/EULAR recommendations for the management of AS, which do not suggest a role for CSDMARD treatment for predominantly axial manifestations of AS.

There is also growing evidence that patients with axSpA, particularly those early in the course of their disease and with a raised CRP, respond better to treatment with TNF blockers, probably indicating that symptoms at the start are mostly caused by inflammation whereas later on pain and other symptoms might be present for different reasons.

2.6.1.d Administration of TNF-blocking agents

- Screening before starting anti-TNF therapy

The usual precautions and contraindications for biological treatment should be followed. In short: screening for latent tuberculosis infection should be performed according to local guidelines (a tuberculin skin test (Mantoux test) and/or an interferon-gamma release assay) and chest X-ray examination. In high-risk groups or in those vaccinated against tuberculosis (Bacille Calmette–Guérin (BCG) vaccination), the interferon-gamma release assay should be considered. When a positive reaction occurs, appropriate prophylaxis should be given, such as treatment with isoniazid, before the start of biological agents, according to local guidelines.

Screening for hepatitis B should be considered in populations at risk.

Patients who have congestive cardiac failure (New York Heart Association class III–IV) and patients who were recently diagnosed with cancer should not start anti-TNF therapy.

Furthermore, it is important to inform patients that they cannot receive immunisation with attenuated, live-virus preparation (such as yellow fever) during treatment with anti-TNF agents.

In patients who want to become pregnant treatment with anti-TNF can be continued until conception. Continuation throughout the pregnancy will be discussed depending on the disease activity/severity.

2.6.1.e Adverse events of anti-TNF therapy for SpA

Adverse events in patients with axSpA and other SpA treated with TNF blockers do not differ from those seen in other diseases, such as RA and Crohn's disease (CD). However, patients with axSpA are normally younger and have been less frequently treated with glucocorticoids or immunosuppressive drugs than patients with the other two diseases. Thus, the number and severity of side effects can be expected to be at least no higher than with other chronic inflammatory diseases, and might even be lower; comparative data on this are not available. Infections including opportunistic infections may occur in a small percentage of patients. The occurrence of demyelination and deterioration of congestive heart failure has been reported occasionally.

An approximately twofold risk of development of non-melanoma skin cancer has been reported.

In patients with axSpA, the clinical inefficacy of infliximab or adalimumab correlates with the presence of low serum trough infliximab or adalimumab levels and the presence of antibodies against infliximab or adalimumab (de Vries et al, 2007; de Vries et al, 2009). Moreover, development of anti-infliximab antibodies can precede an infusion reaction. The mechanism of the decrease in efficacy can be explained by lower serum trough infliximab or adalimumab levels, caused by neutralising antibodies against the idiotypic of infliximab and adalimumab, and enhanced clearance due to immune complex formation of antibodies against biological agents. Another TNF blocking agent, etanercept, does not seem to have high immunogenic properties, although response rates are similar among the four TNF blockers (de Vries et al, 2009).

Reports of the treatment of RA and of CD suggest that combining infliximab with another immunosuppressive agent such as azathioprine, methotrexate or glucocorticoids, might reduce side effects, such as allergic reactions. These immunosuppressive agents might even prevent intolerance to infliximab treatment, most probably owing to the inhibition of anti-infliximab antibodies. A recent study indicated that a combination of infliximab with methotrexate in AS was not more effective and did not reduce side effects compared with infliximab alone. It has also to be kept in mind that these drugs are added to infliximab to avoid side effects (production of antibodies) but do not have efficacy on disease activity itself in AS, which differs from their use in RA and CD.

Contradictory results have been reported with regard to the influence of csDMARDs in the anti-TNF alpha drug retention rate: Lie et al reported a decreased risk of 12 to 29% in the drug discontinuation over time in

patients with comedication with csDMARDs, while Sepriano et al did not find any significant effect on such drug survival.

Therefore, for now, there is not sufficient evidence to combine TNF-blocking agents with immunosuppressive drugs in SpA.

2.6.2 IL-17 blocking agents

The recent published data on IL-17 inhibitors has been a major breakthrough in the treatment of this disease. Secukinumab, a monoclonal antibody directed against IL17A, has proven to improve signs and symptoms rapidly and in a high percentage of patients in patients with AS (nr-axSpA studies are ongoing), both in biologic-naïve patients and in patients refractory to TNF alpha blockers. Identically to TNF alpha blockers, there are no data yet to support the claim that this treatment also have structure-modifying effects in patients with AS (Baeten et al, 2015; Sieper et al, 2016). Secukinumab has been approved in Europe for AS, at the dosage of 150 mg subcutaneously administered, at a frequency of once a month after five weekly injections.

2.6.3 Other biological agents.

The cytokine interleukin 1 has also been a target in the development of new drugs. So far the interleukin 1 receptor antagonist, anakinra, has been shown to be effective in the treatment of patients with RA. Only two open studies have examined the efficacy of anakinra in AS, with conflicting results (Haibel et al, 2005b). At present, anakinra does not seem to have a role in the treatment of AS.

Abatacept and rituximab were evaluated in small open-label studies. No relevant clinical responses were seen, particularly as these trials were not placebo-controlled. Moreover, the results were certainly disappointing for the subgroup of patients for whom previous TNF blockade had failed.

Treatments targeting the interleukin 6 pathway (tocilizumab) were tested in formal randomised placebo-controlled studies, but failed to show a significant improvement over placebo (Sieper et al, 2014).

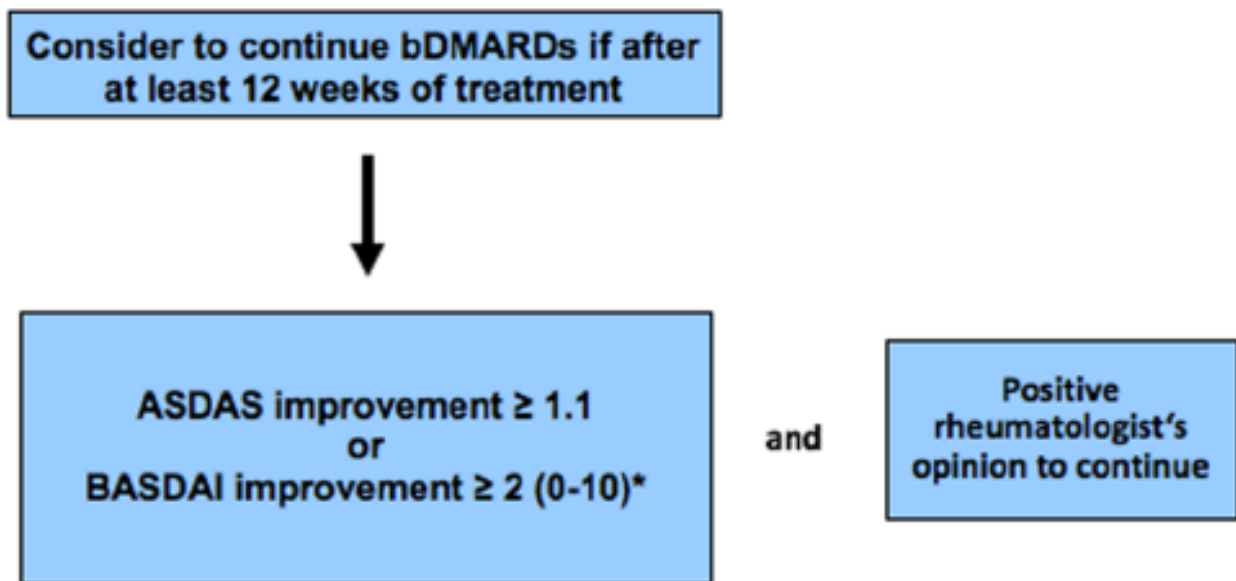

2.6.4 Monitoring bDMARDs in axSpA

For the monitoring of bDMARDs in axSpA, both the BASDAI and the ASAS core set (in the domains of patient global assessment, pain, function and spinal mobility) for clinical practice should be used regularly. ASDAS may have better discriminative characteristics than patient-reported outcomes.

Discontinuation of anti-TNF therapy should be strongly considered in non-responders after 12 weeks' treatment (figure 15). Response is defined as improvement of (a) at least 50% or 2 units (on a 0–10 scale) of the BASDAI, (b) in addition to an expert opinion that treatment should be continued, again relying not only on the patients' subjective symptoms. The same attitude may be considered with the IL17 blocker.

A decrease of ASDAS of ≥ 1.1 (figure 1) is defined as clinically important improvement and ≥ 2.0 as a major improvement. Similar recommendations or guidelines have been published by national societies such as the Canadian Rheumatology Association and the British Society of Rheumatology or in the USA (www.spondylitis.org/physician_resources/guidelines.aspx) following the reasoning of the ASAS recommendations, only with slight modifications.

Figure 14 ASAS-EULAR recommendations for the continuation of bDMARDs. ASDAS, Ankylosing Spondylitis Disease Activity Score; axSpA, axial spondyloarthritis; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; bDMARD, biological disease modifying anti-rheumatic drug. (Adapted from van der Heijde et al, *Ann Rheum Dis* 2017;76:978-991.)

* Either ASDAS or BASDAI can be used, but the same measure per patient

2.7 Other non-biological agents.

A small molecule, or “targeted DMARD”, is under development in AS. This molecule, Apremilast, works as an inhibitor of the phosphodiesterase 4, and is orally administered. Only results of a proof of concept study are yet available.

Recently, preliminary results obtained with tofacitinib, an orally administered JAK inhibitor, have been reported.

3 Management of extraspinal manifestations in axSpA

The extraspinal or extra-articular manifestations (EAMs) of axSpA can be divided into so-called SpA concept-related EAMs and non-concept-related diseases (figure 16).

Figure 16 Extra-articular manifestations in spondyloarthritis. SpA, spondyloarthritis; TNF, tumour necrosis factor.

Extra-Articular Manifestations in Spondyloarthritis

Concept related

Eye-skin-gut-urogenital

- Frequent (20-60%)
- Clinical inflammation
 - At any moment of the disease evolution
- Sometimes related to axial or joint inflammation
- Effect of classical SpA drugs

=> Effect of TNF-blockers proven

Not concept related

Lung-kidney-heart-nerve

- Very rare (1%)
- Mostly subclinical
 - Long standing disease
- Not related to locomotor disease
- No effect of classical SpA drugs

=> Effect of TNF-blockers unknown

The concept-related EAMs, such as uveitis, psoriasis and IBD, are usually also a manifestation of chronic immune-mediated inflammation occurring at another (related) body system (eye, skin, gut). Their management is closely related to the treatment of the rheumatological component of the disease; this will be discussed in the next part of this chapter, as well as in the online 'in-depth-discussions'. The non-related manifestations, such as aortic insufficiency, pulmonary fibrosis and renal amyloidosis, may occur in a small percentage of patients with axSpA, mostly in longstanding disease. Conventional SpA treatments do not seem to affect these rare conditions and it remains to be seen whether these complications can be avoided by earlier treatment with bDMARDs. It would, however, seem logical that efficient abrogation of longstanding inflammation might prevent consequences such as amyloidosis. When these manifestations are present, they should be treated similarly to those caused by other underlying diseases.

4 Management of osteoporosis in axSpA

Osteoporosis is a common manifestation in axSpA, not only as a consequence of limited mobility, but also because of local and general inflammation. Vertebral fractures often occur in this relatively young and male population. The role of treatment such as bisphosphonates is not yet elucidated. No studies have been performed in patients with axSpA to determine the efficacy of bisphosphonates on bone mineral density, or the influence of these drugs on progressive ankylosis of the spine and syndesmophyte formation.

More recently, it has been shown that treatment of active axSpA with TNF blockers induces a rapid improvement of bone mineral density after just 6 months of treatment with infliximab or etanercept, but not with placebo.

5 Cardiovascular comorbidity in axSpA

Cardiovascular comorbidity in axSpA causes increased mortality, as described in detail in chapter 17. The risk of atherosclerosis is doubled in this disease, which results in a higher risk of myocardial infarction. Additionally, conduction disturbances of the atrioventricular node related to HLA-B27 are increased in AS, as well as the risk of aortic insufficiency due to cardiac inflammation in longstanding disease. Therefore, the EULAR recommendations for cardiovascular risk management also apply to axSpA (chapter 17).

6 Surgical intervention in axSpA

Hip arthritis occurs in up to one-third of patients with AS most often early in the disease (first 10 years) and is more common if the disease starts early in life. A total hip replacement is necessary in about 5% of all patients with AS and is associated with good long-term results. Although patients with axSpA are normally younger than others undergoing hip replacement, the revision rate is no higher. There is no major difference in durability or complications between cemented and non-cemented hip prostheses, but non-cemented total hip replacement is preferable in younger patients because revision is technically easier.

The ankylosis of the spine results in obvious limitation of movement and elasticity. The reduced flexibility in combination with osteoporosis of the spine, as a consequence of lack of movement and of local and systemic inflammation, renders the spine susceptible to a variety of complications, including fracture and dislocation, sometimes even after a minor trauma (Gelman and Umber, 1978).

Spinal instability can also occur as a consequence of a severe Anderson lesion (disco vertebral erosions and destruction). Pain and/or neurological involvement are indications for fusion operations. Severe complications, such as neurological problems, occur in about 2–4% of patients (Fox et al, 1993). Atlantoaxial and atlanto-occipital subluxation and spinal stenosis can be other reasons for surgical interventions. In cases of severe and invalidating thoracolumbar kyphosis a correction can be performed by lumbar osteotomy in specialised centres (Van Royen et al, 1999).

7 Axial manifestations in patients with psoriasis or IBD

If axSpA occurs in association with psoriasis or IBD, the treatment algorithm is similar to that for patients with primary axSpA. NSAIDs should be used with caution in patients with IBD (see section 14.2).

8 Predominant peripheral SpA

Peripheral arthritis and enthesitis occur in about 30–40% of patients with axSpA (usually in a transient and/or relapsing form), but are in general characteristic for the whole group of SpA, where they occur in a typical pattern involving predominantly the lower limbs asymmetrically. Part of the rationale for dividing SpA into predominantly axial or peripheral SpA lies in the differences of the treatment options for these two major disease manifestations (see also ASAS/EULAR Recommendations for the treatment of axSpA). Contrary to axial disease (where csDMARDs are not efficacious and NSAIDs are the only conventional medical treatments), drugs like sulfasalazine, methotrexate and leflunomide seem to play a role in the treatment of the peripheral manifestations of SpA. Apart from these oral drugs, local steroid injections are successfully used in daily practice to treat peripheral arthritis, dactylitis and some forms of enthesitis, especially in cases of localised, monoarticular or pauciarticular joint involvement. When these conventional treatment options fail, bDMARDs may be indicated. In the following discussion each drug class will be presented separately for the SpA subgroups with predominant peripheral involvement: we will discuss psoriatic disease, arthritis associated with IBD and reactive arthritis.

8.1 Psoriatic arthritis

Psoriatic arthritis (PsA) is associated with various patterns of rheumatological manifestations, which is reflected by the currently most used CASPAR classification criteria (figure 17). In the initial description by Moll and Wright, five different rheumatological patterns were described: polyarticular (RA-like) and oligoarticular (SpA-like) peripheral joint involvement, distal interphalangeal joint involvement, axial disease and arthritis mutilans. Lately, the relevance of this sub classification has been challenged as patients may change from one pattern to the other spontaneously or as a consequence of treatment. Instead of classifying patients within a specific subgroup, different domains are now recognised within the full spectrum of psoriatic disease, and treatment is tailored to the importance of specific domains, such as peripheral arthritis, enthesitis, dactylitis, spondylitis, skin and nail disease. Ideally, treatment should always be aimed at improving all manifestations of the disease. In daily practice this can be achieved by treating patients with multiple drugs with different actions that can be safely combined together, or by the use of a single agent, that can deal with both skin and joint manifestations.

Figure 15 Classification criteria for psoriatic arthritis (CASPAR). PsA, psoriatic arthritis. (Adapted from Taylor et al, Arthritis Rheum 2006;54:2665–73.)

Classification of Psoriatic-Arthritis: CASPAR Criteria

To meet the CASPAR criteria for PsA, a patient must have inflammatory articular disease (joint, spine, or enthesal) and score ≥ 3 points based on these categories.	
	POINTS
1. Evidence of psoriasis Current psoriasis Personal history of psoriasis Family history of psoriasis	2 or 1 or 1
2. Psoriatic nail dystrophy Pitting, onycholysis, hyperkeratosis	1
3. Negative test result for rheumatoid factor	1
4. Dactylitis Current swelling of an entire digit History of dactylitis	1 or 1
5. Radiologic evidence of juxta-articular new bone formation Ill-defined ossification near joint margins on plain x-rays of hand/foot	1

CASPAR, Classification criteria for Psoriatic Arthritis
Taylor W et al. Arthritis Rheum 2006;54:2665-2673

About 8–40% of patients with psoriasis will develop arthritis; the prevalence of PsA is estimated at 0.3% of the population, the incidence at 6–8/100 000. In about 63% of cases, psoriasis is already present before the arthritis occurs; in 19%, both manifestations occur simultaneously, but in up to 18% of patients, a typical arthritis develops before any sign of classic psoriasis. In these last cases, diagnosis may be difficult and physicians should pay particular attention to discrete skin and/or nail lesions. For peripheral joint manifestations, the pattern of involvement is often asymmetrical; this is of course evident in cases of SpA-like, oligoarticular, lower limb involvement, but even in polyarticular disease (which has recently been considered to be the most prevalent manifestation), the symmetry is usually not as pronounced as in typical RA. Distal interphalangeal joint joints of the hands and feet may be involved in all classic subtypes. Dactylitis and enthesitis, manifestations typical for the whole group of SpA, are also often found in patients with PsA.

No good correlation is found between the severity of skin involvement and arthritis.

Whereas there are only limited—good quality—data on the treatment of PsA with csDMARDs, the previous decade has witnessed a wealth of clinical trial data with multiple biological agents, mainly belonging to the

class of TNF α blockers. Treatment guidelines for PsA have been published by the international group GRAPPA (Group for Research and Assessment of Psoriasis and Psoriatic Arthritis) (figure 18) and by EULAR (figure 19).

Figure 16 Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) 2015 Treatment Recommendations for Psoriatic Arthritis.. CsA, ciclosporin A; DMARD, disease-modifying antirheumatic drug; IA, intra-articular; LEF, leflunomide; MTX, methotrexate; NSAIDs, non-steroidal anti-inflammatory drugs; PUVA, psoralen and ultraviolet A treatment; SSZ, sulfasalazine; TNF, tumour necrosis factor; UVB, ultraviolet B. (Reproduced from Coates and Ritchlin, *Arthritis Rheumatol.* 2016;68:1060-71).

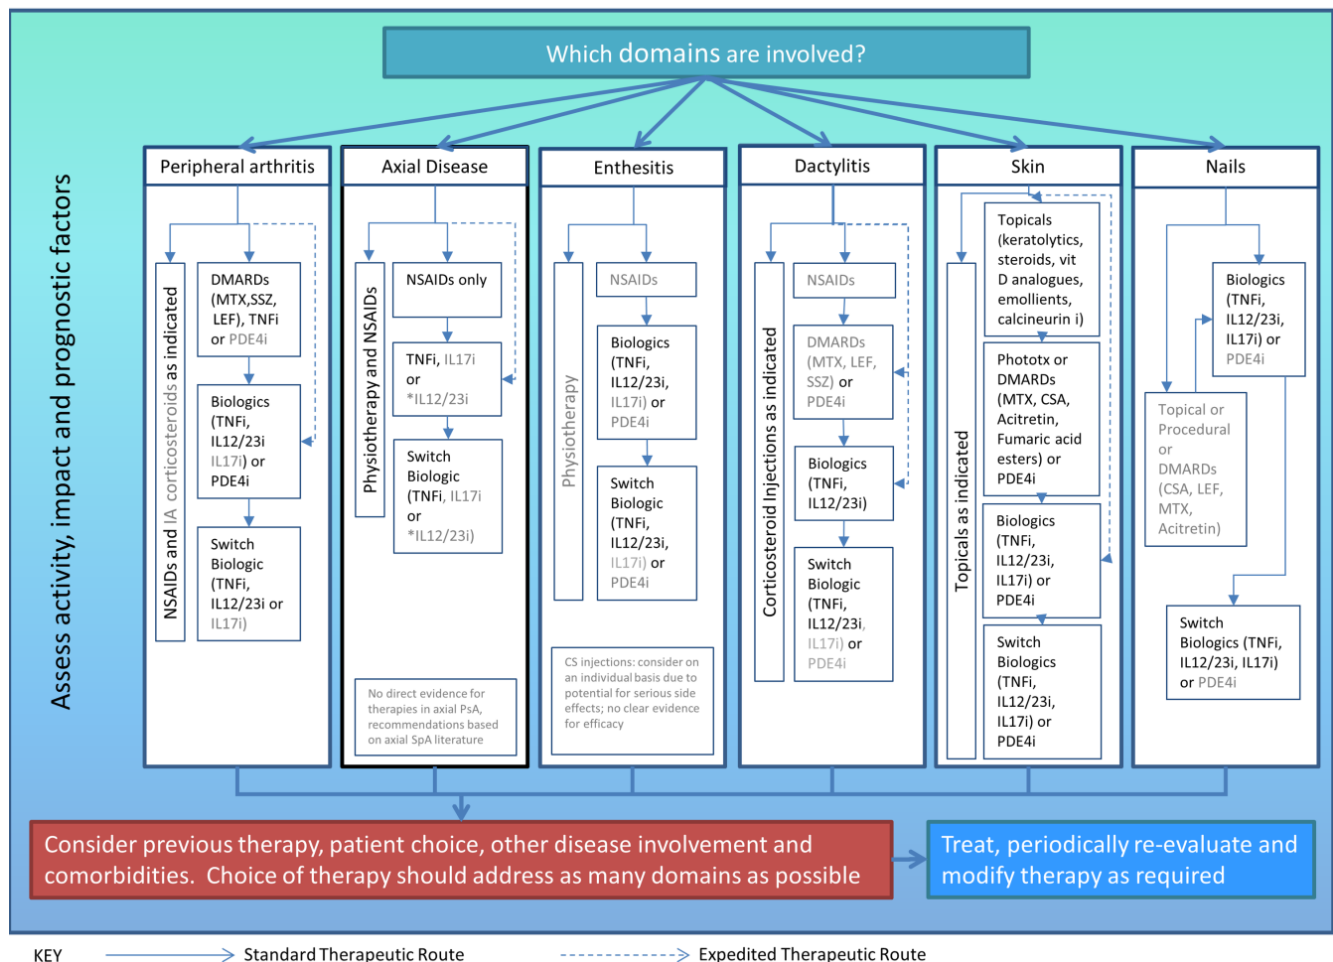

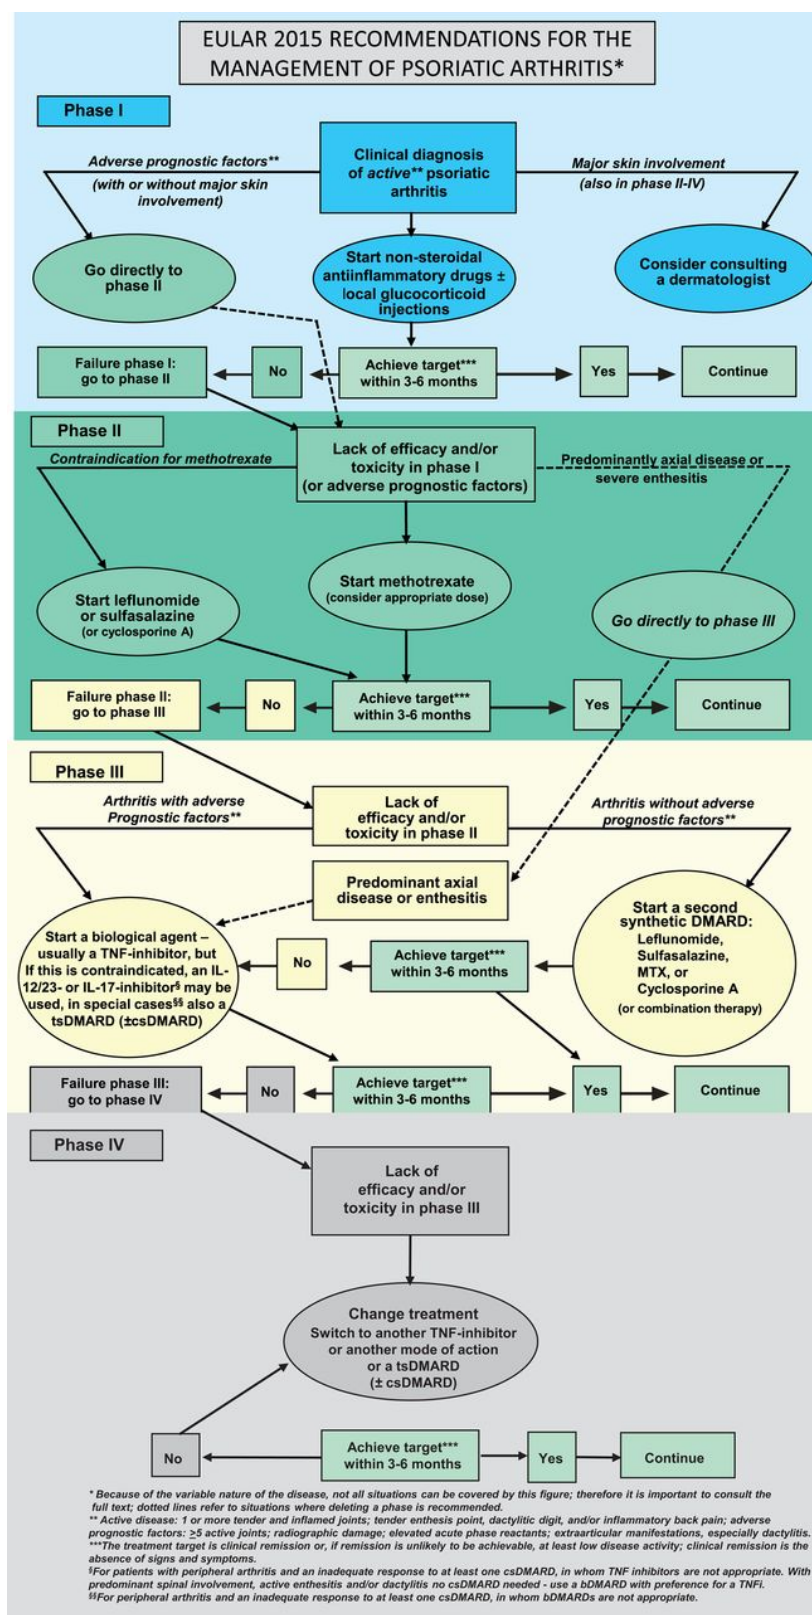

Figure 17 European League Against Rheumatism (EULAR) recommendations for the management of psoriatic arthritis with pharmacological therapies: 2015 update. (Reproduced from Gossec et al, Ann Rheum Dis. 2016;75:499-510).

8.1.1 NSAIDs

NSAIDs are widely used in daily clinical practice for the initial treatment of any type of arthritis, and are also the first level of treatment in the GRAPPA and EULAR PsA treatment algorithm. Some studies show that conventional NSAIDs have good efficacy in the treatment in PsA; no randomised controlled trial has been performed with Cox-2- specific NSAIDs. Improvement of the skin was not seen in these studies, and there are even reports of an exacerbation of the skin manifestations in patients treated with NSAIDs.

8.1.2 Glucocorticoids

Efficacy and side effects of oral or parenteral glucocorticoids have not been studied systematically in PsA. Nevertheless, registry data suggest that (low-dose) systemic steroid therapy is quite frequently used in daily practice. Because dose reduction or withdrawal of glucocorticoids can induce a flare of psoriasis, these drugs should be used with caution in patients with PsA and, if necessary, at a low dose and only for a limited time. Intra-articular injections of glucocorticoids are often used in clinical practice, especially for monoarthritis and oligoarthritis. An injection through affected skin should be avoided.

8.1.3 csDisease-modifying antirheumatic drugs

The use of csDMARDs for PsA has historically followed the treatment schedules used in RA for patients with peripheral arthritis and psoriasis. As discussed above, csDMARDs do not play a role in the treatment of axial SpA manifestations, but they have some proven efficacy in pSpA, with data available for sulfasalazine, leflunomide, methotrexate and ciclosporin. However, clinical trials with csDMARDs in PsA were often non-controlled, used different classification and improvement criteria (making comparison between trials difficult) and included only small number of patients with PsA, in an attempt to demonstrate roughly similar efficacy to RA. Interestingly, leflunomide was the only drug with proven efficacy in a double-blind, placebo-controlled study (Kaltwasser et al). In the recently published placebo-controlled, MIPA study (Methotrexate In Psoriatic Arthritis), methotrexate failed to show significant effects on arthritis (Kingsley et al), which is counterintuitive as most rheumatologists in daily practice would use methotrexate as the first line of csDMARD treatment in PsA (which is also incorporated in the EULAR treatment algorithm). In the RESPOND trial (Baranauskaite et al, 2012), comparing methotrexate monotherapy with a combination of methotrexate and infliximab in patients with relatively early PsA (2.8–3.7 years), an ACR 20 response in 66.7%, an ACR 50 response in 39.6% and an ACR 70 response in 18.8% of patients receiving monotherapy was seen. Data from the NOR-DMARD register concluded that the 6-month efficacy of sulfasalazine, leflunomide and methotrexate was similar.

Data indicating that combination treatment of methotrexate and ciclosporin is quite effective for arthritis and psoriasis are limited; combination treatment with leflunomide and methotrexate showed a significantly better effect on arthritis than monotherapy, without increasing the risk of adverse reactions. Available data are

conflicting as to whether these drugs have an influence on radiological progression. In an Italian study on 174 patients with PsA, intake of methotrexate resulted in a good long-term effect on peripheral arthritis, but radiological joint damage scores deteriorated by 83%. However, when historic patient cohorts treated with methotrexate were compared, a more recent patient group demonstrated better efficacy both on signs and symptoms as well as on the retardation of structural damage. Although this cannot be formally proved, these observed effects are probably the consequence of a higher weekly dose of methotrexate and an earlier start of csDMARD treatment (Chandran et al, 2008). For all these drugs some improvement of psoriasis has also been reported, with ciclosporin and methotrexate probably being the most effective. Antimalarial agents and oral or injectable gold have no role in the treatment of PsA.

8.1.4 TNF-blocking agents

All five TNF-blocking agents approved for the treatment of patients with active AS, have also demonstrated remarkable effectiveness in the treatment of patients with active PsA, (figure 20), leading to an approved indication for use in PsA in the EU and the USA.

Figure 18 American College of Rheumatology (ACR) 20 response in patients with psoriatic arthritis treated with tumour necrosis factor α (TNF α) blockers. Five different studies with no head-to-head comparison. (Adapted from 1Antoni et al, *Ann Rheum Dis* 2005;64:1150–7; 2Mease et al, *Arthritis Rheum* 2004;50:2264–72; 3Mease et al, *Arthritis Rheum* 2005;52:3279–89; 4Kavanaugh et al, *Arthritis Rheum* 2009;60:976–86; Mease P et al, *Ann Rheum Dis* 2014;73:48–55. 5. Mease P et al. *Ann Rheum Dis* 2014;73:48–55

In all studies continuation of previous csDMARD treatment (usually methotrexate) was permitted, but not necessary for inclusion. Interestingly, the level of response was similar in patients receiving anti-TNF monotherapy, compared with those receiving a TNF blocker in combination with a csDMARD. However, these data do not allow us to conclude if—for a patient with newly diagnosed PsA—there would be an advantage for combination therapy with csDMARD plus an anti-TNF biological agent over monotherapy with either the csDMARD or the TNF blocker alone. For the approved TNF-blocking agents, there is no difference in the dose and administration schedule compared with treatment of patients with AS.

Contrary to the data with csDMARDs, there is convincing evidence that TNF-blocking agents can halt structural damage in pSpA, as shown by stable erosion and joint narrowing scores of the radiographs of hands and feet in patients treated with a TNF blocker, compared with further progression in the placebo group.

Few studies are available on the treatment of enthesitis. Evidence suggests, that NSAIDs, glucocorticoid injections and physiotherapy improve the symptoms caused by enthesitis. There is no proof that csDMARDs have any efficacy on this type of lesion, which is why these drugs are not incorporated in the GRAPPA treatment guidelines. Although different instruments (enthesitis indices) were used in the pivotal studies on anti-TNF agents in PsA (which makes comparison difficult), there is clinical consensus that all these biological agents can treat refractory inflammation at the site of the enthesis when a standard dosing schedule is used. Interestingly, in the PRESTA (Psoriasis Randomized Etanercept Study in subjects with psoriatic Arthritis) trial, 50 mg etanercept given twice weekly had no greater effect on the rheumatic manifestations (with—in addition to the known efficacy on peripheral arthritis—a clear improvement of enthesal manifestations and dactylitis) than the standard rheumatological dose of 50 mg weekly.

Similarly, there are few studies on the treatment of dactylitis. Methotrexate, sulfasalazine, ciclosporin and leflunomide may all have some efficacy. Mostly based on expert opinion, systemic glucocorticoids and intra-articular glucocorticoid injections seem to have some role in the treatment of dactylitis. Finally, it has been shown that all four TNF blockers improve the signs and symptoms of active dactylitis.

Remarkable efficacy is also seen in the skin and nail manifestations of PsA. With monoclonal antibodies (infliximab, adalimumab and golimumab) given at the standard 'rheumatological' dose, Psoriasis Area and Severity Index (PASI) 75 skin responses are usually found in up to 60% of patients. With etanercept 50 mg weekly, clinical trials both in PsA and in psoriasis showed lower PASI 75 responses; in psoriasis studies a higher dose of 50 mg twice weekly yielded a better skin response (this 'skin dose-response' was also seen in the above-mentioned PRESTA trial). For comparison, in the placebo-controlled PsA study with leflunomide, the active drug achieved only an ACR 20 and a PASI 75 response at week 24 in 36% and 17% of patients, respectively.

8.1.5 New biological agents, and other agents, in PsA

Interleukin (IL)-12 and IL-23 have important roles in the pathophysiology of psoriasis. Ustekinumab is a human monoclonal antibody with high affinity for the p40 subunit of IL-12 and IL-23. Based upon two large, double-blind, placebo-controlled, phase III studies, the drug was approved for the treatment of psoriasis. The compound was also investigated in PsA. McInnes et al, (2013) reported the 1-year results of a phase III study in patients naïve for TNF blockers comparing ustekinumab at two different doses (45 and 90 mg) with placebo, administered subcutaneously at week 0, week 4 and every 12 weeks thereafter. At week 24, an ACR 20 response was seen in 22.8%, 42.4% and 49.5% of patients treated with placebo, ustekinumab 45 mg or 90 mg, respectively. When the two ustekinumab groups were combined, an ACR 20 response was seen in 46.0%, whereas more stringent improvement criteria, such as ACR 50 and ACR 70 response, were seen in 26.4% and 13.2%, respectively. The known efficacy on skin disease was confirmed, with 59.9% of patients in the combined ustekinumab group achieving a PASI 75 skin response (compared with only 11.0% in the placebo group). Another RCT, (Ritchlin et al, 2014) included 312 adults with active PsA who were randomised to ustekinumab 45 mg or 90 mg at week 0, week 4, q12 weeks or placebo at week 0, week 4, week 16 and crossover to ustekinumab 45 mg at week 24, week 28 and week 40. Efficacy was assessed in all patients, anti-TNF-naïve (n=132) patients and anti-TNF-experienced (n=180) patients. More ustekinumab-treated (43.8% combined) than placebo-treated (20.2%) patients achieved ACR20 at week 24 ($p<0.001$). Among patients previously treated with ≥ 1 TNF inhibitor, sustained ustekinumab efficacy was also observed (week 24 combined vs placebo: ACR20 35.6% vs 14.5%). Interestingly, post-hoc data recently published also suggested a beneficial effect of ustekinumab in the treatment of axial disease in patients with AS. Furthermore, pooled data of Psummit 1 and 2 demonstrated a beneficial structural effect of the drug. Ustekinumab is now approved for PsA treatment in Europe.

Multiple anti-IL-17 agents have been and are being investigated in psoriatic disease. Recent publications on the use of brodalumab, ixekizumab and secukinumab—all monoclonal antibodies targeting the IL-17 pathway—have demonstrated PASI 75 skin responses in the range of 75–80% (Leonardi et al, 2012; Papp et al, 2012; Papp et al, 2013). At present, the 2 pivotal studies with secukinumab in PsA have been published and that drug is approved for PsA in Europe, and the 2 other agents are under investigation for PsA (and AS) in phase III studies. In the first pivotal study 606 patients with psoriatic arthritis were randomly assigned in a 1:1:1 ratio to receive intravenous secukinumab (at a dose of 10 mg per kilogram) at weeks 0, 2, and 4, followed by subcutaneous secukinumab at a dose of either 150 mg or 75 mg every 4 weeks, or placebo. ACR20 response rates at week 24 were significantly higher in the group receiving secukinumab at doses of 150 mg (50.0%) and 75 mg (50.5%) than in those receiving placebo (17.3%) ($p<0.001$ for both comparisons with placebo). In a second study, a phase 3, double-blind, placebo-controlled study, 397 patients were randomly assigned to receive secukinumab 300 mg (n=100), 150 mg (n=100), 75 mg (n=99), or placebo (n=98). A

significantly higher proportion of patients achieved an ACR20 at week 24 with secukinumab 300 mg (54 [54%] patients; odds ratio versus placebo 6.81, 95% CI 3.42-13.56; $p<0.0001$), 150 mg (51 [51%] patients; 6.52, 3.25-13.08; $p<0.0001$), and 75 mg (29 [29%] patients; 2.32, 1.14-4.73; $p=0.0399$) versus placebo (15 [15%] patients). Secukinumab is now approved for PsA treatment in Europe.

As for TNF blockers studies, in trials with ustekinumab and secukinumab continuation of previous CSDMARD treatment (usually methotrexate) was permitted, and the observed level of response was similar in patients receiving biological drug monotherapy, compared with those receiving the combination with a CSDMARD.

Abatacept, a selective T cell costimulation modulator, was investigated in a 6-month, double-blind, placebo-controlled, phase II study. Three different dosing regimens (3 mg/kg, 10 mg/kg and 30/10 mg/kg (two initial doses of 30 mg/kg, followed by 10 mg/kg) were compared with placebo. Intravenous drug was administered at days 1, 15 and 29, and every 4 weeks thereafter. ACR 20 responses were seen in 19%, 33%, 48% and 42% in the placebo, abatacept 3 mg/kg, abatacept 10 mg/kg and abatacept 30/10 mg/kg groups, respectively (with the two higher dosing groups showing a statistically significant difference with placebo). Physical function also improved significantly at 10 mg/kg, and less joint damage was demonstrated by MRI evaluation (Mease et al, 2011). These results suggest that the approved abatacept dosage for RA, may also be an effective treatment option for PsA.

Over recent years, small molecules inhibiting intracellular signalling pathways have entered the therapeutic field of RA, with tofacitinib, an orally administered JAK inhibitor, being the first of this new therapeutic class to receive marketing approval in the USA for treatment of moderate-to-severe RA. Efficacy of this drug in psoriasis has been demonstrated (Bachelez et al, 2015) and results of phase III studies with tofacitinib in PsA are awaited.

Apremilast, another small molecule inhibiting phosphodiesterase 4, has been investigated in a number of clinical trials in PsA. In one of the phase III randomized clinical trial, 504 patients were randomised (1:1:1) to placebo, Apremilast 20 mg twice a day (BID) or Apremilast 30 mg BID. At week 16, significantly more Apremilast 20 mg BID (31%) and 30 mg BID (40%) patients achieved ACR20 versus placebo (19%) ($p<0.001$). Efficacy of Apremilast in PsA has been confirmed also in patients with active skin disease : in patients with baseline psoriasis body surface area involvement $\geq 3\%$, significantly more Apremilast 30 mg twice daily patients achieved 50% reduction from baseline Psoriasis Area and Severity Index score (41%) versus placebo (24%; $p=0.0098$) at week 16. Apremilast is now approved for PsA treatment in Europe.

8.1.6 Global recommendations for management of PsA

Recently the international GRAPPA group and EULAR published updated recommendations for the treatment of PsA, including the use of TNF blockers (figures 18 and 19). The GRAPPA group takes an approach that

focuses on the different domains of psoriatic disease, and describes evidence-based treatments for each domain. When instituting a certain treatment, the efficacy should be monitored by the physician with the aim of maximally controlling all aspects of the disease. As mentioned in the introduction to this paragraph, the physician will—in an individual patient—treat with a combination of drugs that can be combined safely together, or will use a single drug capable of tackling the different disease manifestations. The EULAR management recommendations mainly deal with peripheral arthritis. A step-up treatment schedule is proposed, starting with NSAIDs, over csDMARDs (with methotrexate as anchor drug), then biological agents, usually a TNF blocker. In this algorithm the physician will take prognostic factors, toxicity and inadequate response to the prior level of treatment into account. Usually—when standard (csDMARD) treatments such as methotrexate, sulfasalazine, ciclosporin or leflunomide over a period of 3 to 6 months have failed—the recommendations for the initiation of a TNF blocker require a disease activity with at least one or more swollen and tender joint. Treatment decisions about patients with predominant severe enthesitis or dactylitis have to be made on an individual basis, but there is consensus that biological agents targeting TNF are probably the first-choice drugs. In cases of predominant axial involvement, the ASAS/EULAR treatment guidelines for axial SpA should be followed.

A clear effect of treatment with bDMARDs or tsDMARDs should be seen after at least 12 weeks of treatment, with rheumatological manifestations exhibiting an earlier response than skin and/or nail disease.

8.2 IBD-associated SpA

The treatment of the peripheral arthritis in patients with IBD is, in general, the same as for other SpA, but concomitant active gut inflammation, both in CD and ulcerative colitis (UC), may complicate the traditional treatment approach. We will again review the different treatment modalities.

8.2.1 NSAIDs

As with other SpA, NSAIDs are the first choice of treatment for axial disease, but this drug class should also be started for peripheral arthritis. However, in IBD, they should be given with caution because some data suggest that they may cause an exacerbation of intestinal symptoms, mainly in UC; these relapses of quiescent IBD in the large intestine may appear after a few days of NSAID treatment in susceptible patients. The role of Cox-2 selective agents such as celecoxib and etoricoxib, is not entirely clear. Although these agents seem to have a better safety profile for upper gastrointestinal tract lesions, there are no systematic data on their safety in IBD. Nevertheless, two prospective controlled studies of patients with IBD and rheumatic symptoms who were evaluated for IBD flares while receiving Cox-2 selective agents versus placebo, suggested no higher incidence of flares with the active drug compared with placebo (El Miedany et al, 2006; Sandborn et al, 2006). Based on these data, a short trial of a Cox-2 selective agent may be considered in patients with quiescent IBD who have active rheumatological symptoms related to SpA.

It is well known that a significant percentage of patients with SpA have subclinical (microscopic) inflammatory gut lesions resembling those seen in CD. Since chronic use of NSAIDs can lead to ulcerations in the stomach and the small and large intestine, one might hypothesise that some of these lesions are the consequence of administration of this type of drug. However, virtually all ileocolonoscopy studies in patients with SpA have shown the absence of any association between these gut lesions and the use of NSAIDs (similar percentage of gut lesions in patients with and without NSAID use). Moreover, most NSAID-induced gut lesions are found proximal to the ileum, whereas the majority of subclinical IBD lesions are found in the ileocaecal region and colon.

8.2.2 Glucocorticoids

Intra-articular glucocorticoid injections may be beneficial in monoarticular or oligoarticular flares. Oral glucocorticoids may reduce peripheral synovitis, but have no effect on axial symptoms (as mentioned above). Their systematic use is justified only if they are required for control of the bowel disease. Controlled ileal release (CIR) budesonide, a glucocorticoid that has high affinity for the glucocorticoid receptor but low systemic activity owing to extensive first-pass hepatic metabolism, may be used as an alternative to prednisone when treating bowel symptoms; placebo-controlled trials have shown that CIR budesonide at 9 mg/day is effective in patients with mild to moderately active Crohn's ileitis and/or right colon involvement. No trials in SpA have yet been performed, and the effect of CIR budesonide on peripheral arthritis or spondylitis was not examined in the CD trials. However, a placebo-controlled trial comparing prednisolone 7.5 mg versus CIR budesonide 3 or 9 mg daily in patients with RA yielded similar efficacy results for the prednisolone and the budesonide 9 mg group (Kirwan et al, 2004); this suggests that if CIR budesonide is prescribed for active gut disease, there might also be beneficial effects on peripheral arthritis.

8.2.3 csDMARDs

Comparable to their use in PsA, csDMARDs have been used by clinicians for the treatment of peripheral arthritis associated with IBD, but again, well-designed, controlled studies are lacking.

Sulfasalazine, which has been successfully used to treat colonic inflammation in UC and CD, has been found to be effective in the treatment of the peripheral arthritis accompanying SpA, especially if intestinal inflammation is present. It may also have a favourable effect on the peripheral arthritis in IBD, but, as mentioned before, will not influence axial symptoms. Despite the clinical effect of sulfasalazine on peripheral joint manifestations in SpA, the drug does not seem to prevent the development of IBD.

Azathioprine and its principal metabolite 6-mercaptopurine have been used successfully for more than 30 years in patients with CD for (1) induction of gastrointestinal remission in steroid-refractory disease, (2) as a

steroid-sparing agent, (3) in fistulising disease and (4) for maintenance treatment. However, despite some efficacy in RA, the drug has not been studied for treatment of the arthritis of CD or UC.

Low-dose methotrexate successfully used in the treatment of RA and in some cases of refractory IBD, has not yet been shown to be effective in joint inflammation associated with CD or UC.

Leflunomide is an isoxazole derivative approved for the treatment of RA and PsA. It has only been studied in a small open-label trial of 12 patients with CD who were intolerant to azathioprine: clinical improvement was noted in eight of 12 patients, suggesting that further study in controlled trials is warranted.

Gold salts, D-penicillamine and antimalarial drugs are ineffective.

8.2.4 TNF-blocking agents

In the 1990s, it was shown that treatment with a single infusion of infliximab is highly effective in the short-term treatment of intestinal involvement in treatment-resistant CD (figure 22), even resulting in the closure of enterocutaneous fistulae.

Figure 19 Efficacy of anti-TNF α therapy in chronic inflammatory bowel disease. Ileocolonoscopy in Crohn's disease. (A) Before treatment with infliximab: presence of important ulcerations. (B) After treatment with infliximab: disappearance of inflammation and ulcerations. TNF, tumour necrosis factor.

Efficacy of Anti-TNF- α -Therapy in Chronic Inflammatory Bowel Disease

Ileocolonoscopy in a patient with Crohn's disease

A : before anti-TNF therapy: colitis and ulcers
B : after treatment with infliximab: normal findings

As a consequence of these pilot findings, multiple placebo-controlled, phase III studies were performed investigating the efficacy and safety of anti-TNF agents in active IBD. Both induction schedules and maintenance regimens were studied, the latter showing that maintenance treatment in moderate to severe CD prolonged the response and remission of the disease (Rutgeerts, 2004). Infliximab and adalimumab are approved by the European Medicines Agency for the treatment of CD and UC, and golimumab has recently received approval for the treatment of UC. Although phase III studies with certolizumab in CD showed efficacy, the drug has only been approved for use in the USA, but not in the European union.

The first observations that infliximab treatment might also be useful for the treatment of resistant peripheral joint and axial manifestations in patients with CD, came from an open pilot study: four patients with treatment-resistant or fistulising CD, but at the same time also active axial and/or peripheral SpA, were treated with 5 mg/kg infliximab. Beside remission of gut inflammation, a significant improvement of articular and axial symptoms was seen in all patients. In one patient the disease flared after approximately 3 months, but re-treatment with the same dose of infliximab induced a new remission (figure 23).

Although no formal placebo-controlled study has been performed in SpA associated with IBD, there is little doubt that infliximab is also highly efficacious in this indication. In the ACCENT I trial, evaluating the efficacy of a re-treatment regimen of infliximab in patients with active CD, maintenance treatment also resolved extra-intestinal manifestations, such as arthritis. An Italian open study evaluated the efficacy of a loading dose regimen of 5 mg/kg infliximab in 24 patients with SpA associated with active (n = 16) or quiescent (n = 8) CD. Infliximab improved both gastrointestinal and overall articular symptoms (axial disease, peripheral arthritis, enthesitis). In patients with inactive CD at baseline, infliximab prevented IBD flares during the follow-up period.

Figure 20 Effect of anti-TNF α therapy on articular symptoms in Crohn's disease. Efficacy of infliximab (intravenous infusion of 5 mg/kg body weight; infusions were given at weeks 0, 16 and 34) in a patient with CD and spondyloarthritis. Effect on C-reactive protein (CRP) level and the number of swollen joints (SJC). Gastrointestinal and articular disease flared approximately 3 months after infliximab treatment; re-treatment with the same dose induced a new remission. TNF, tumour necrosis factor. (Reproduced with permission of Elsevier from Van den Bosch et al, *Lancet* 2000;356:1821–2.)

The combined published evidence in the gastroenterology and rheumatology literature shows that there is little doubt that monoclonal antibodies targeting TNF are effective for treatment of both gut and joint lesions.

A particular scientific challenge, however, is that more TNF α blockers are effective in axSpA than they are in IBD. Etanercept is an example of such a drug with discordant efficacy. Despite its very good efficacy in the treatment of AS, an 8-week, randomised, double-blind, placebo-controlled trial showed no signs of efficacy in patients with active CD. Braun et al (2007) surveyed all data on the occurrence of IBD in patients with AS exposed to anti-TNF therapy during different placebo-controlled trials and their open-label extension studies: flares or new onset of IBD were seldom seen in patients treated with infliximab, but the reactivation of IBD (especially of UC) was relatively common with etanercept (figure 24); interpretation of the adalimumab data was difficult because of the significantly smaller number of patient-years. The biological basis for this

discrepancy is still being studied: reasons may include differences in bioavailability and pharmacodynamics, as well as cell biological effects (induction of apoptosis) that may differ from one TNF α -blocking agent to another.

Figure 21 Flares or new forms of IBD in patients with AS treated with TNF-blocking agents. Low but different incidence of acute IBD in patients with AS receiving anti-TNF α therapy. AS, ankylosing spondylitis; IBD, inflammatory bowel disease; TNF, tumour necrosis factor. (Adapted from Braun et al, *Arthritis Rheum* 2007;57:639–47.)

Effect of Anti-TNF α -Therapy on Articular Symptoms in Crohn's Disease

8.2.4 Other bDMARD agents

Ustekinumab is a human monoclonal antibody with high affinity for the p40 subunit of IL-12 and IL-23. A double-blind, placebo-controlled, cross-over trial was conducted in 104 patients with moderate-to-severe Crohn's disease. Patients were given subcutaneous placebo at weeks 0-3, then ustekinumab at weeks 8-11; subcutaneous ustekinumab at weeks 0-3, then placebo at weeks 8-11; intravenous placebo at week 0, then ustekinumab at week 8; or intravenous ustekinumab at week 0, then placebo at week 8. Clinical response rates for the combined groups given ustekinumab and placebo were 53% and 30% ($P = .02$), respectively at weeks 4 and 6, and 49% and 40% ($P = .34$), respectively at week 8. In a subgroup of 49 patients who were previously given infliximab (neither primary nor secondary non-responders), clinical response to ustekinumab was significantly greater than the group given placebo ($P < 0.05$) through week 8. Ustekinumab is now approved for Crohn's disease treatment in Europe.

An integrin antagonist, vedolizumab binds to the $\alpha_4\beta_7$ integrin which is expressed specifically by a subset of gastrointestinal-homing T lymphocytes. The binding of $\alpha_4\beta_7$ integrin to mucosal address in cell adhesion

molecule-1 expressed on the surface of mucosal endothelial cells is a crucial component of the gut-selective homing mechanism for lymphocytes. The results of two trials (one in Crohn's disease and another in ulcerative colitis) have led to the approval of this drug for both forms of IBD. The trial in Crohn's disease included 368 patients who were randomly assigned to receive vedolizumab or placebo at weeks 0 and 2. At week 6, a total of 14.5% of the patients 1 who received vedolizumab and 6.8% who received placebo were in clinical remission. In the ulcerative colitis trial, 374 patients received vedolizumab (at a dose of 300 mg) or placebo intravenously at weeks 0 and 2. A response was defined as a reduction in the Mayo Clinic score (range, 0 to 12, with higher scores indicating more active disease) of at least 3 points and a decrease of at least 30% from baseline, with an accompanying decrease in the rectal bleeding sub score of at least 1 point or an absolute rectal bleeding sub score of 0 or 1. Response rates at week 6 were 47.1% and 25.5% among patients in the vedolizumab group and placebo group, respectively (difference with adjustment for stratification factors, 21.7 percentage points; 95% confidence interval [CI], 11.6 to 31.7; $P < 0.001$).

8.3 Reactive arthritis

Reactive arthritis is also discussed in chapter 14, Infection and Arthritis. NSAIDs are also the mainstay of treatment for reactive arthritis. This can, as for the other SpA, be supplemented by joint injections with glucocorticoids. Activation of a (latent) infection in the joint has not been reported. Data on the use of csDMARDs are limited. In most patients reactive arthritis is a self-limiting disease and therefore DMARD treatment should only be considered if chronic arthritis persists for more than 4–6 months.

As already discussed above, sulfasalazine was effective for peripheral arthritis in a placebo-controlled study of patients with SpA, including those with reactive arthritis. Azathioprine and other csDMARDs have been used with some success in patients with severe reactive arthritis; however, no controlled data are available. Several case reports and small open-label studies have reported a good efficacy of TNF-blocking agents for the treatment of reactive arthritis refractory to conventional treatment, without reactivation of the triggering infection. But again, no controlled data are available.

Reactive arthritis is triggered by a preceding gastrointestinal or urogenital infection, and bacteria or parts of bacteria can be detected in the synovial fluid and synovial membrane of patients, which raises the question as to whether a short or long-term (eg, 3 months) antibiotic treatment regimen might be of some benefit. However, neither regimen has been found to be effective for arthritis. Only when *Chlamydia trachomatis* is detectable in the urogenital tract should this infection be treated with an antibiotic for 10–14 days to prevent relapses of arthritis.

Since it was suggested that undifferentiated peripheral SpA may be an expression of reactive arthritis, in which the triggering infectious agent cannot be detected, an aetiological attempt was carried out in three studies using antimicrobial drugs. In two of the studies, a 3-month course of ciprofloxacin or doxycycline did not

produce favourable results in comparison with placebo. Recently, Carter et al tested the combination of doxycycline and rifampicin in a small group of patients with undifferentiated SpA. These two drugs were administered for a 9-month period. A significant improvement was seen in pain, morning stiffness, swollen and tender joint count in comparison with the patients of the control group who were given doxycycline only. These promising data certainly need to be confirmed in larger studies.

Summary points

- ➔ Treatment of the predominant axial and predominant peripheral manifestations of the spondyloarthritis (SpA) partly differs and partly overlaps.
- ➔ Physiotherapy is the most important non-pharmacological treatment in SpA.
- ➔ Non-steroidal anti-inflammatory drugs (NSAIDs), tumour necrosis factor (TNF) blockers and IL-17 inhibitors are the only effective drugs for the treatment of axial SpA while conventional disease-modifying antirheumatic drugs may have a role in the management of peripheral SpA.
- ➔ Consequently, NSAIDs should be preferred for the treatment of axial SpA. The aim should be to achieve patients free of symptoms.
- ➔ TNF-blocker treatment is indicated in axial Spondyloarthritis (axSpA) and psoriatic arthritis (PsA) after failure of conventional treatment.
- ➔ IL-17 blockers are indicated in ankylosing spondylitis (AS) after failure of conventional treatment.
- ➔ TNF blockers and IL-17 are highly effective for the treatment of AS (TNF blockers also in non-radiographic SpA). A significant improvement of disease activity, function, spinal mobility and reduction of acute phase reactant is fast and can normally be seen days to a few weeks after the start of treatment.
- ➔ TNF blockers also reduce active inflammation of sacroiliac joints and spine in patients with axSpA as shown by MRI.
- ➔ TNF blockers are also highly effective for the treatment of PsA, as well as IL12/23 blocker and IL17 blocker. There is evidence for a good efficacy for other forms of peripheral SpA.
- ➔ Structural damage (erosions/joint space narrowing) is stopped by TNF blockers, IL12/23 blocker and IL17 blocker in PsA, while existing data does not allow to suggest that TNF blockers prevent ankylosis in patients with AS. There is evidence that NSAIDs can inhibit ankylosis.
- ➔ For extra rheumatic manifestations of SpA several bDMARDs (e.g. TNF blockers, but also IL 17 and IL23 blockers) have shown to be effective for the treatment of inflammatory bowel disease, psoriasis and in the reduction of flares of uveitis. Conversely, it is worth noting that etanercept and IL-17 blockers are not effective for the treatment of IBD; furthermore, etanercept has not proved to reduce uveitis flares.

Management of spondyloarthritis

Anna Moltó, Pascal Claudepierre, Irene van der Horst-Bruinsma

A previous version was co-authored by Irene van der Horst-Bruinsma, Mirjam de Vries, Filip Van den Bosch, Joachim Sieper, Hiltrun Haibel, Herman Mielants and Philippe Carron

IN-DEPTH DISCUSSION I

**The Management of Acute Anterior Uveitis associated
with SpondyloArthritis**

Acute anterior uveitis (AAU) is the most common form of uveitis, with an annual incidence rate of about 8 cases per 100000 population (1). The disease primarily affects only the anterior chamber of the eye. AAU is a prominent manifestation of spondyloarthritis with a strong link to HLA-B27, occurring in 30-40% of patients with axial Spondyloarthritis (axSpA). Acute inflammation of the uvea can be the first presenting symptom of the disease. In a study among 433 patients with different types of uveitis, 44 cases (almost 10%) of SpA were detected, whereas others showed a percentage up to 50% of previously undiagnosed cases of SpA among uveitis patients (2-4). The occurrence of AAU is increased in the HLA-B27 positive population, with a lifetime cumulative incidence of 0.2 % in the general population compared with 1% in the HLA-B27 positive population (5). In an observational survey of 902 SpA patients with a HLA-B27 positivity of 76%, uveitis prevalence was 32.2% (95% confidence interval [95% CI] 29.1–35.3%), and was the most common extraarticular feature of SpA. Factors independently associated with uveitis were HLA-B27 positivity (adjusted odds ratio [OR_{adj}] 2.97 [95% CI 1.83–4.81], $P < 0.0001$) and disease duration (OR_{adj} 1.28 [95% CI 1.16–1.41], $P < 0.0001$ for ≥ 10 years). (6) Banares and colleagues also described a relationship between anterior uveitis and bowel inflammation (in 60% of patients with AS-related uveitis), with a close relationship between the recurrence of uveitis and the presence of chronic intestinal inflammation (7)

An attack of AAU has a sudden onset and is typically unilateral (although in subsequent flares the other eye may become involved): local redness, photophobia, but most of all ocular pain are the cardinal symptoms. Inflammation can lead to debris, which accumulates in the anterior chamber and may cause papillary and lens dysfunction with blurring of vision. In some cases – when adequate treatment is delayed – glaucoma and severe visual impairment may occur, but most of the time, with local treatment, the uveitis subsides over a period of 6 to 12 weeks.

Figure 1: Characteristics of Acute Anterior Uveitis (reproduction from the ASAS slide kit)

Eye: Acute Anterior Uveitis in Spondyloarthritis

- Acute onset
- Unilateral
- Anterior
- Spontaneous remission
- Recurrent
- Related to HLA B27

In SpA patients with sudden symptoms of a painful, red eye, it is recommended to refer the patient to the ophthalmologist as soon as possible (figure 1).

Treatment of Uveitis

In most cases AAU can be successfully treated by the ophthalmologist with local treatment with corticosteroids and cycloplegic agents (mydriatics). Sometimes subconjunctival injections with corticosteroids are necessary to control inflammation in the anterior chamber. In most cases there is no residual visual impairment.

There seems to be consensus among ophthalmologists that in patients with 3 or more flares of AAU during a 1-year period or with recurrence of inflammation close to cessation of the topical therapy, further systemic treatment is indicated. In such cases oral corticosteroids (up to 60 mg daily) and/or immunosuppressive drugs may become necessary. Because of the low prevalence of uveitis, new systemic treatments have historically been implemented into clinical practice based upon their success in controlling other autoimmune inflammatory diseases, with subsequent anecdotal evidence based on small case studies published by uveitis specialists.

NSAIDs

NSAIDs are the cornerstone of pharmacologic treatment in patients with axSpA. They were however also used (before the emergence of topical corticosteroids) in the treatment of uveitis (8-11). In a study by Fiorelli et al, 59 patients with recurrent anterior uveitis were treated with continuous oral NSAID therapy (celecoxib: n=30; diflunisal: n=29) (12). In both groups the average number of relapses decreased from 2,84 attacks per person-year follow-up before start of systemic NSAID therapy to 0,53 attacks while on treatment ($p<0,001$). Patients remained in remission for an average of 18,22 months.

Sulfasalazine

There is some evidence that the use of sulfasalazine reduces the recurrence rate of AAU (13,14): in this open, prospective study the number of uveitis flares decreased from 3,4 in the pre-treatment year to 0,9 ($p=0,007$). Benitez-del-Castillo et al randomised 22 AS patients with recurrent attacks of AAU to receive either sulfasalazine (n=10) or no treatment (n=12) (15). During a follow-up period of 36 months, a statistically significant difference in favour of sulfasalazine was observed regarding the number of recurrences; new episodes of uveitis in the sulfasalazine group were also less severe.

Methotrexate

In severe chronic, non-infectious uveitis, a number of immunomodulatory drugs are introduced by ophthalmologists in order to control inflammation and avoid undesirable side effects of chronic high-dose, oral corticosteroid therapy. In a survey among uveitis specialists (16), inquiring about practice patterns regarding

the prescription of corticoid-sparing therapy, methotrexate was the most commonly used initial treatment for anterior, intermediate, and posterior/panuveitis (85%, 57%, and 37%, respectively). However, given the fact that methotrexate is not efficacious for the treatment of axial symptoms of SpA, and the potential side effects of this drug, it does not seem a logical treatment choice in patients with recurrent attacks of AAU associated to axial SpA. It could be considered in patients with SpA and predominant peripheral synovitis, where methotrexate could – despite the lack of controlled studies on its efficacy – be a treatment option.

Biologic DMARDS:

- **Anti-TNF agents**

In the previous decade, the advent of TNF-blockers has dramatically changed our treatment algorithm of patients with active SpA. Not only do these drugs have a profound effect on both axial and peripheral manifestations of SpA, but they also have a beneficial impact on other typical locomotor manifestations such as enthesitis and dactylitis, and finally also on the SpA extra-articular manifestations. At this moment, 5 different anti-TNF agents are indicated for the treatment of signs and symptoms of axSpA and PsA: etanercept (a soluble TNF-receptor fusion protein), infliximab (only for AS and PsA), adalimumab and golimumab (all anti-TNF monoclonal antibodies), and certolizumab (an anti-TNF Fab-fragment conjugated to PEG).

Infliximab is an adequate treatment of SpA, decreases the recurrence rate of uveitis and is effective as treatment for refractory uveitis (17). In contrast to systemic treatment with infusions, intraocular injections with infliximab are toxic, inducing intraocular inflammation (18,19). The efficacy of etanercept on uveitis is doubted, as etanercept does not seem to prevent a relapse in combination with methotrexate (20) and it was suggested that etanercept might even trigger attacks of uveitis (21). However, a comparison of three randomised studies with etanercept in AS showed a lower number of cases with uveitis in the etanercept-treated patients compared with placebo (22) indicating that etanercept does inhibit the recurrence of uveitis. An analysis of 4 placebo-controlled studies and 3 open-label studies with TNF-blocking agents in AS (where attacks of uveitis were reported by the patients) showed a frequency of flares of anterior uveitis in the placebo-group of 15.6 per 100 patient-years, compared with 7.9 per 100 patient-years in the etanercept group and only 3.4 per 100 patient-years in the infliximab-treated patients (figure 2) (23).

Figure 2: Decreased incidence of Acute Anterior Uveitis with anti-TNF (reproduction from the ASAS slide kit)

Decreased Incidence of Acute Anterior Uveitis (AAU) in Patients on Anti-TNF α -Therapy

Both etanercept and infliximab were statistically significant better than placebo; infliximab was more, although not significantly, effective than etanercept. A more recent study from France analysed retrospectively the frequency of anterior uveitis relapses before and after treatment with any of the three TNF blockers (24). A clear and significant reduction of uveitis relapses was observed when treatment with either infliximab or adalimumab was started; however, in case of etanercept therapy, no change in the relapse rate was seen.

Reports on the efficacy of adalimumab for uveitis are based on a large, prospective study in 1250 AS patients that received open-label treatment for up to 20 weeks (25): 15 uveitis flares per 100 patient-years were noted before start of adalimumab treatment; the overall rate of flares was reduced with 51% in all patients with better results seen in those patients that had a prior history of uveitis. In another study, AS patients that were treated with adalimumab because of high disease activity, were also screened by an ophthalmologist regarding uveitis. This study demonstrated a significant decrease (73%) of the recurrence rate of uveitis during adalimumab treatment (26).

Recent reports indicate that golimumab and certolizumab also seem to be effective for the treatment of refractory uveitis in patients suffering from immune-mediated inflammatory diseases, including axSpA (27-29). In a post-hoc analysis of a Certolizumab vs. placebo randomized trial in patients with axSpA: 38 of 218 certolizumab-randomized patients (17.4%) and 31 of 107 placebo-randomized patients (29.0%) had past uveitis history at baseline. The rate of uveitis flares was significantly lower in the certolizumab group (3.0 [95%

confidence interval (95% CI) 0.6-8.8] per 100 patient-years) than in placebo (10.3 [95% CI 2.8-26.3] per 100 patient-years) and were similar between AS (4.4 [95% CI 2.3-7.7] per 100 patient-years) and nr-axial SpA (5.6 [95% CI 2.9-9.8] per 100 patient-years) in the 96-weeks extension follow-up period (30).

Finally, recent American recommendations for ophthalmologists considered that infliximab or adalimumab may be used as corticosteroid-sparing treatment for patients with chronic uveitis resulting from seronegative spondyloarthropathy or with severe, vision-threatening or debilitating uveitis requiring systemic immunosuppressive agents or as adjunctive therapy to corticosteroid treatment in acute disease (31).

- **Other bDMARDs:**

Secukinumab, an IL-17 has been reported to be efficacious in the treatment of uveitis in a phase 2 clinical trial, where 37 patients with active non-infectious uveitis requiring a corticosteroid-sparing immunosuppressive therapy were randomized to 3 different doses of **secukinumab**. Higher secukinumab doses lead to higher responder rates and remission rates (32)

No data has been reported yet with regard to the effect of IL12/23 inhibitors in SpA-related uveitis.

Conclusion

It can be concluded that in most cases, attacks of acute anterior uveitis respond very well to (local) treatment by the ophthalmologist. Continuous use of NSAIDs (when indicated for the rheumatological manifestations) and/or sulfasalazine treatment may decrease the number of recurrent flares. In cases of refractory uveitis or a high uveitis recurrence rate, treatment with TNF blocking agents can be successful, especially if the treatment is indicated for high disease activity of SpA. Adalimumab and infliximab (and probably also the other monoclonal antibodies) seem to be more effective in lowering the recurrence rate of uveitis compared to etanercept.

IN-DEPTH DISCUSSION II

Choice of biologic DMARDs in relation to extra-articular manifestations in Spondyloarthritis

Spondyloarthritis (SpA) is a chronic inflammatory disease with either predominant axial symptoms of the spine and sacroiliac joints (axial SpA, including ankylosing spondylitis) or predominant peripheral manifestations, such as arthritis, enthesitis, or dactylitis (peripheral SpA). Next to these spinal and articular symptoms, many patients with SpA also suffer from extra-articular manifestations (EAMs).

Spondyloarthritis-concept related EAMs include anterior uveitis (25-30%), psoriasis (10-25%) or inflammatory bowel disease (IBD) (5-10%). The treatments, used for the rheumatological manifestations of the disease, such as NSAIDs, DMARDs and TNF-blocking agents may have a differential effect on these EAMs, and therefore the presence of these manifestations should be taken into account when taking therapeutic decisions.

Uveitis.

Acute anterior uveitis is an acute attack with inflammation of the uvea and can be the first presenting symptom of the disease. In a study among 433 patients with different types of uveitis, 44 cases (almost 10%) of SpA were detected, whereas others showed a percentage up to 50% of previously undiagnosed cases of SpA among uveitis patients (1-3). The occurrence of acute anterior uveitis is increased in the HLA-B27 positive population, with a lifetime cumulative incidence of 0.2 % in the general population compared with 1% in the HLA-B27 positive population (4).

The attacks of uveitis are usually recurrent and unilateral. The symptoms are sudden ocular pain with redness and photophobia. Inflammation can lead to debris, which accumulates in the anterior chamber and may cause papillary and lens dysfunction with blurring of vision. In some cases glaucoma and severe visual impairment occurs if adequate treatment is delayed, but most of the time, with local treatment, the uveitis subsides spontaneously within 3 months. In SpA patients with sudden symptoms of a painful, red eye, it is recommended to refer the patient to the ophthalmologist as soon as possible.

In most cases acute uveitis can be successfully treated by the ophthalmologist with local corticosteroids and mydriatics. Sometimes high oral dosage of prednisone (up to 60 mg daily) is necessary to control inflammation. In most cases there is no residual visual impairment.

Some data suggest that continuous use of NSAID's show efficacy for uveitis flares. There is some evidence that the use of sulfasalazine reduces the recurrence rate of uveitis (5, 6). Other immunosuppressive drugs used by the ophthalmologists to treat refractory uveitis, such as azathioprine and methotrexate, do not have much efficacy on the disease activity of SpA.

Some TNF-blocking agents, can be used for both indications, active disease of SpA as well as refractory uveitis. Infliximab is an adequate treatment of SpA, decreases the recurrence rate of uveitis and is effective in refractory uveitis (7, 8). The efficacy of etanercept, on uveitis is doubted, as etanercept does not seem to prevent a relapse in combination with methotrexate (9) and it was suggested that etanercept might even trigger an attack of

uveitis (10). However, a comparison of three randomised studies with etanercept in AS showed a lower number of cases with uveitis in the etanercept-treated patients compared with placebo (11) indicating that etanercept inhibits the recurrence of uveitis.

An analysis of 4 placebo-controlled studies and 3 open-label studies with TNF agents in AS showed a frequency of flares of anterior uveitis in the placebo-group of 15.6 per 100 patient-years, compared with 7.9 per 100 patient-years in etanercept group and 3.4 per 100 patient-years in the infliximab treated patients (8). The attacks of uveitis during these studies were reported by the patients and no follow up studies or ophthalmologic controls were performed.

Reports on the efficacy of adalimumab for uveitis are based on a large, prospective study in 1250 AS patients that received open-label treatment for up to 20 weeks (12): 15 uveitis flares per 100 patient-years were noted before start of adalimumab treatment; the overall rate of flares was reduced with 51% in all patients, with better results seen in those patients that had a prior history of uveitis. In a prospective study, AS patients were treated with adalimumab because of high disease activity, and screened by an ophthalmologist for uveitis as well. This study demonstrated a significant decrease (73%) of the recurrence rate of uveitis (13) during adalimumab treatment.

Recent reports show that golimumab (14,15) and certolizumab also seem to be effective in refractory uveitis (16).

It can be concluded that in most cases, attacks of anterior uveitis respond very well to (local) treatment by the ophthalmologist. In cases with refractory uveitis or a high uveitis recurrence rate, treatment with TNF blocking agents can be successful, especially if the treatment is indicated for high disease activity of SpA. Adalimumab and infliximab seem to be more effective in lowering the recurrence rate of uveitis compared to etanercept, and certolizumab and golimumab are effective in refractory uveitis.

Psoriasis

Psoriasis is a common skin disease with plaque lesions and nail deformities and is primarily treated by the dermatologist. Psoriatic arthritis occurs in 5-20% of the people with psoriasis and can present as a symmetrical polyarthritis, resembling rheumatoid arthritis, but with additional involvement of the DIP-joints (17). Axial disease occurs in about 5% of the psoriasis patients with asymmetrical sacroiliitis in one-third of the cases and spondylitis without sacroiliitis in the rest. Enthesitis and dactylitis are common, especially in the oligoarticular form of the disease. In SpA, patients with psoriatic arthritis excluded, psoriasis occurs in approximately 5-10%.

In case of scaling skin lesions or nail changes suspicious for psoriasis in SpA it is recommended to refer the patients to a dermatologist.

Skin manifestations of psoriasis usually respond very well to local corticosteroids or PUVA therapy.

In case of psoriatic arthritis, NSAID's and intra-articular injections with corticosteroid are effective in mono- or oligoarthritis (18), but these treatments do not influence skin disease. Methotrexate is widely used in daily clinical practice for the treatment of skin disease and arthritis, despite the lack of randomized controlled trials to support this (18). Leflunomide is also effective for both psoriasis and peripheral arthritis, but not for the axial manifestations of SpA (19).

TNF alfa blockers, such as infliximab, etanercept, adalimumab, certolizumab and golimumab are efficacious on the skin and nail lesions of psoriasis (table 1) (15). In some cases treatment of SpA with TNF blocking agents can result in a new paradoxical manifestations of psoriasis, such as palmoplantar pustulosis (20). New biologicals, such as the interleukin (IL) 12/23 inhibitor ustekinumab (21) and the anti-IL17A monoclonal antibody secukinumab (22), are very effective for psoriasis and psoriatic arthritis (and for AS for secukinumab while results of placebo-controlled trials with ustekinumab in patients with AS are awaited).

Inflammatory Bowel Disease

Inflammatory Bowel disease includes Crohn's disease and ulcerative colitis and is primarily treated by the gastro-enterologist. Approximately 10% of the IBD patients develop SpA. On the other hand, the chance of SpA patients to develop IBD is 5-10%. Asymptomatic inflammatory bowel disease is described in a high percentage of SpA patients (up to 60%) and can be detected by endoscopy of the colon and terminal ileum (23). During follow up studies, it appeared that up to 20% of the SpA patients with chronic gut inflammation eventually develop Crohn's disease (24). Another indication that diseases as SpA and IBD show some overlap comes from a study on serological markers of IBD. In this study, a high percentage (55%) of AS patients without abdominal complaints had a positive tests for pANCA, ANCA or Omp-C ASCA antibodies (25). In case of persistent or frequently recurring diarrhoea and/or blood or mucus production with the stools it is advised to refer SpA patients to the gastro-enterologist in order to perform an ileocolonoscopy.

Treatment of IBD by the gastro-enterologist is based on immunosuppressive drugs and anti-TNF. Although good quality evidence is lacking, the use of NSAIDs is assumed to worsen colitis manifestations, therefore it is advised that SpA patients with IBD should minimise the use of these drugs, perhaps with the exception of celecoxib, which does not seem to increase the risk of exacerbation of IBD (26). The use of sulfasalazine can be beneficial for both SpA as well as IBD. Other immunosuppressive drugs used for the treatment of IBD, such as azathioprine, have no proven efficacy in SpA (27). Of the TNF blocking agents only infliximab and adalimumab are effective in both Crohn's disease and ulcerative colitis (28-31). Golimumab shows efficacy in ulcerative colitis but is not tested in Crohn's disease (32) whereas certolizumab is effective in Crohn's disease but not tested for ulcerative colitis (33). Etanercept was evaluated in a small trial for Crohn's disease and did not show

efficacy (34), while there is even data to suggest that new manifestations of IBD might occur during treatment of SpA with etanercept (35-37) (table 1).

Regarding new mode-of-action biologics, ustekinumab was shown to be effective in patients with moderate to severe Crohn's disease that was resistant to TNF antagonists (38); patients with an initial response had significantly increased rates of response and remission with ustekinumab as maintenance therapy. Interestingly, the anti-IL17A agent secukinumab was ineffective in a placebo-controlled proof-of-concept study in 59 patients with Crohn's disease, with unexpectedly also higher rates of adverse events compared with placebo (39).

Table 1: TNF inhibitors and extra-spinal manifestations in SpA

	Arthritis	Uveitis	Ulcerative colitis	Crohn's disease	Psoriasis

1

Conclusions

In SpA physical exercises and NSAID's are the choice of treatment. In case of peripheral arthritis, sulphasalazine can be added as a useful DMARD. In case of insufficient response to NSAIDs, TNF blockers are very effective in SpA. These drugs all work very well on the axial manifestations as well as on arthritis, enthesitis and dactylitis. For skin and nail psoriasis, TNF antagonists also have a proven beneficial effect and other biological drugs targeting the IL-12/23 or IL-17 pathway have also been approved for treatment of moderate-to-severe psoriasis.

Concerning the treatment of other extra spinal manifestations, anterior uveitis can be treated adequately by the ophthalmologist with local treatment. In refractory cases or a high recurrence rate, treatment with

adalimumab and infliximab seems to be more effective for this indication compared to etanercept, with emerging positive data for golimumab and certolizumab, pointing towards a global better efficacy of monoclonal antibodies compared to the TNF-receptor fusion protein. The same phenomenon is observed in cases of SpA with concurrent IBD. The use of NSAIDs should be limited to short, intermittent courses. When anti-TNF therapy becomes necessary in SpA patients with IBD, monoclonal antibodies should be prescribed, since etanercept was shown to be ineffective for the treatment of Crohn's disease.

In second line of biologic drugs, after anti TNF alpha failure, ustekinumab and secukinumab can be used in case of active psoriasis, probably also in case of active or recurrent uveitis; in case of active IBD, secukinumab should be avoided and ustekinumab preferred. Overall, it is important to realize that in SpA extra-articular manifestations do occur frequently and should be taken into account when treatment choices have to be made (40).

Measuring disease activity and damage in inflammatory arthritis

Patrick Verschueren, Nathalie Berghen and Pedro Machado

A previous version was coauthored by Pernille Bøyesen, Pedro Machado, Désirée van der Heijde and Mikkel Østergaard

LEARNING OUTCOMES

- ➔ Describe and explain which assessments are available to assess disease activity and damage in patients with rheumatoid arthritis, axial spondyloarthritis and psoriatic arthritis
- ➔ Explain the difference between response and status criteria
- ➔ Apply assessments in the follow-up of patients in clinical practice
- ➔ Interpret data from clinical trials using the discussed assessments

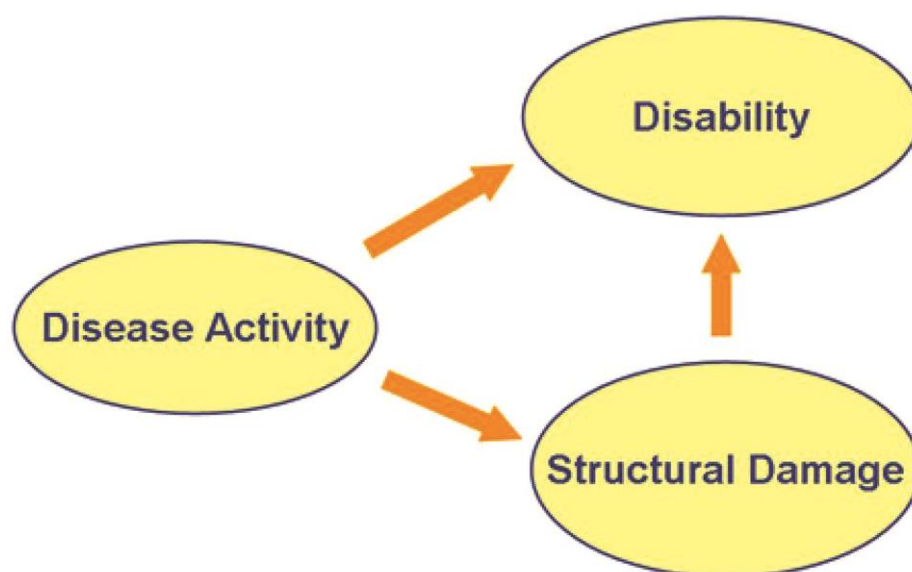

In daily clinical practice every clinician is using implicit and explicit assessments. An example of an implicit assessment is 'the patient is doing well', and an example of an explicit assessment is 'on a 10-point scale the patient's global health is 8 (with 10 being the best possible)'. It has been recognised for many years that for optimal treatment, monitoring of outcomes with explicit assessments is essential. This chapter describes the principles of assessment and the most frequently used assessments in monitoring after the diagnosis has been made. The content focuses on the application in clinical practice and the interpretation of published data from studies. For the general introduction, rheumatoid arthritis (RA) has been used as the classical representative of the inflammatory joint diseases. The sections on the specific assessments are tailored towards the three individual diseases: rheumatoid arthritis, axial spondyloarthritis and psoriatic arthritis.

1 General

1.1 Concept of disease activity, function and damage

In RA there is a clear relationship between disease activity, function, and damage (figure 1). Both in early and late disease there is a close relationship between disease activity and (physical) function. Moreover, in all stages, disease activity causes damage that is visible on, for example, radiographs and magnetic resonance imaging (MRI). In longstanding disease there is a close relationship between damage and function. To get a complete picture of the disease, these three aspects (disease activity, function, damage) need to be assessed. The most widely applied instrument to assess function is the Health Assessment Questionnaire (HAQ). The assessment of function is beyond the scope of this chapter (for more detailed information see chapter 9 on pathogenesis and clinical aspects of RA).

Figure 1 Relationship between disease activity, structural damage and disability in rheumatoid arthritis.

Importantly the assessment of disease activity can be based on a clinical evaluation by a health professional (e.g. swollen joint count), on technical investigations (e.g. laboratory tests, imaging, etc.), but also on so-called patient reported outcomes. These are assessments that are reported by the patient, which deal with different aspects of disease activity (e.g., morning stiffness, pain), but also with function as assessed by the HAQ. Patient-reported measures have gained a lot of interest in recent years as these are of great importance to the patient. However, the combination of patient-reported measures with clinical assessments, laboratory and imaging results gives the most complete picture.

1.2 Why is it important to measure (tailor-made treatment)?

It has been shown in several studies that a subjective global assessment of disease activity by doctors underestimates the amount of inflammation (disease activity). This is true, both if the doctor's global assessment (e.g. on a visual analogue scale) is compared with clinical disease activity measures or with inflammation as assessed by ultrasound. A few decades ago it was of less importance if a patient still had some residual disease activity, as no effective treatments were available. Currently, treatments are available that can bring about complete disease remission. To be able to provide optimal treatment to a patient (so called tailor-made treatment) it is important to be well informed about the actual disease activity. The present goal is to help a patient as quickly as possible into longstanding remission. Regular disease activity assessments are necessary to judge if this goal has been reached or whether adjustments to treatment need to be made. For example, the TICORA (Tight Control in RA) trial (Grigor et al, 2004) showed that treatment with predefined goals of disease activity, and adjustment of treatment according to the level of disease activity, resulted in more patients entering remission compared to traditional clinical practice. Other trials applying this so-called "treat-to-target" principle and comparing various treatment strategies with predefined treatment goals are the BeSt trial (BeSt is the Dutch acronym for "Behandelstrategieën", which stands for treatment strategies, Goekoop-Ruiterman et al, 2010) and the Belgian CareRA trial (acronym for "Care for early RA", Verschueren et al, 2016).

Overall, there is a causal relationship between clinically assessed disease activity (e.g., by the number of swollen joints) and the development of damage in joints. This is true even when individual joints are assessed: swelling in a particular joint leads to damage in the same joint. Vice versa, absence of swelling in an individual joint is directly linked to repair of damage in the same joint, while repair does not occur in joints with persistent swelling. However, this relationship is not always as expected. Some patients in clinical remission still show progression of radiographic damage. On the other hand, in some studies (e.g. in the ATTRACT study, Smolen et al, 2005) patients treated with a TNF blocker, especially if in combination with methotrexate, show less radiographic damage even if there is persistent disease activity. More information is needed to understand these data fully. However, this indicates that imaging is important in addition to disease activity assessment for a full understanding of what is happening to a patient.

1.3 Core set (definition)

Many instruments are available to assess disease activity in inflammatory diseases. Before the implementation of core sets, these were all used according to the personal preference of the investigators in various studies. But if different instruments are included in various clinical trials it is hard to compare data across trials. Moreover, if many assessments are included in a clinical trial there are problems with multiple statistical tests, and there is always the risk of presenting only the data with positive results. To overcome these problems, core sets have been defined for the inflammatory diseases. A **core set** is a *group of assessments that should be included and reported in each study as a minimum*. In addition, other measures may be used to examine a specific study question.

The definition and use of core sets has led to a standardisation of clinical trial design and reporting. Core sets are defined for use in studies but sometimes also for use in clinical practice.

1.4 Single versus composite measures (pros and cons)

As the inflammatory diseases are heterogeneous, no single instrument can describe the disease process well for every patient. For example, some patients have a relatively normal erythrocyte sedimentation rate (ESR) or C reactive protein (CRP) with a high number of swollen joints; for other patients this may be the other way round. Examining only the ESR would not give a correct reflection of the level of disease activity in these two patients. But both ESR and the number of swollen joints give some information about the underlying process of inflammation. The many available instruments reflect different parts of the underlying disease process, and several of them overlap partly or largely. This concept has led to the development of **combined disease activity measures (composite scores)**. These combine the information from various instruments that describe the underlying disease process, but with minimum overlap.

In general, composite scores more accurately reflect the overall state of the disease compared to individual measures; this does not dispute the fact that there may be times when single construct measures are more appropriate for judging a specific outcome, because the intervention is directed primarily at one construct and not necessarily meant to produce a global change. The most widely used composite measure is the Disease Activity Score (DAS), which has been shown to have a closer relationship with radiographic progression and function than single variables. Another advantage is that it can be used to better describe disease activity across patients with different expressions of the disease process. Furthermore, the overall advantage of using composite scores is their wider applicability to various groups of patients and the reduction in sample size needed in clinical trials to obtain the same power to detect a difference between groups.

1.5 Response versus status measures

Core sets include individual assessments and in trial reports these should be presented for the group at baseline as well as at follow-up and over the treatment period. This information is presented at a group level and is hard to interpret for a clinician. If the average number of swollen joints is reduced from 12 to seven, what does this tell us about the benefit for an individual patient? Moreover, single instruments do not give the full picture of disease activity. These two factors led to the development of **response criteria**. The application of response criteria demonstrates whether a patient has responded to a certain treatment. The advantage for the interpretation is that the clinician now gets information on how many patients respond to a certain treatment. This can more easily be translated into useful information for making treatment decisions in clinical practice. Response criteria are mainly used in clinical trials and less in clinical practice. The main disadvantage is that response criteria compare only the follow-up assessment with baseline but do not take into account what is happening in between. For example, if a patient shows a sustained response after 2 weeks of treatment or after 50 weeks of treatment, both are counted as responders at the end of the trial at week 52. Thus, time to response and stability of response are important factors that also need to be taken into account.

In order to increase interpretability, disease activity measures require criteria for identifying disease activity states (or status) and improvement (or response criteria). **Response measures** help to determine whether treatments really work—that is, whether they actually produce clinically important improvement—allowing investigators, clinicians, regulators and patients to determine the efficacy (or lack thereof) of a given intervention and to communicate about response using the same metric. **Disease activity states (status measures)** measure clinical disease activity at specific time points and are important for supporting decisions about entry into clinical trials, for supporting treatment changes, and for defining therapeutic goals.

The baseline value always plays an important role during each follow-up assessment if based on a response criterion—for example, at weeks 2, 12, 24, 52 there is always a comparison with the baseline value. Especially with a longer follow-up, this is a disadvantage. In addition, responder status does not give, or only partially gives, information about the level of disease activity reached. Here the adage applies: ‘it is good to be better, but it is better to be good’. To assess if a patient is in a ‘good condition’, or has low disease activity or is in remission or in a ‘patient-acceptable symptom state (PASS)’, various composite measures with validated cut-offs have been developed. The effect of treatment on an individual patient can be best described if the information on both the response and the achieved level of disease activity is used.

PASS is a relatively new concept. This is the maximum level of symptoms (which can be defined separately—for example, pain and function) with which patients consider themselves to be well for a certain period of time. In defining PASS, various definitions for time have been used, ranging from no time specified (current

state), or the next few months, to the rest of the patient's life. Validation of PASS for various diseases, across languages and cultures, and testing for stability over time is underway.

1.6 Answer modalities

For the patient-reported instruments various answer modalities can be used. Most widely used are the (horizontal) visual analogue scale (VAS), the numerical rating scale (NRS) and the verbal rating scale (Likert) (figure 2). The VAS is usually a horizontal line marked at the left and right ends with the two extreme options in wording (e.g. no pain and most extreme pain) and no marks on the line. The patient is asked to tick the line describing his or her situation best. The VAS is usually 10 cm long and can be measured in millimetres or centimetres. The assessment from the left (e.g. no pain) to the tick gives the result. The NRS is a line with numbers reflecting the entire range, most frequently from 0 to 10. At the extremes the same wording is presented as for the VAS. Again the patient is asked to tick the number that describes his or her situation best. The value can be read off immediately. The Likert scale describes the various possibilities with words—for example, no pain, a little pain, moderate pain, severe pain, and very severe pain. The patient selects the word that describes his or her situation best.

Figure 2 Visual analogue scale (VAS), numerical rating scale (NRS), and Likert scale.

The disadvantage of the Likert scale is that it is difficult in multicultural situations to obtain the exact meaning of scale terms in another language. Moreover, the distance between the various categories is not equal and consequently a change from very severe to severe pain is not necessarily the same as an improvement from severe to moderate pain. The theoretical advantage of the VAS is that there are 101 different answer options with possibly higher sensitivity to change. In a comparative study the reproducibility and sensitivity to change of the VAS and NRS were similar. Moreover, patients preferred the NRS over the VAS. Other advantages of the

NRS are that there can be no errors in making a copy (resulting in a line that is no longer exactly 10 cm) or measuring the distance, and that the NRS can also be applied in telephone interviews. Whenever the VAS is further mentioned in this module it could also be replaced by an NRS. In clinical practice, especially, the NRS seems to be the most feasible answer modality (Van Tubergen et al, 2002).

2 Rheumatoid arthritis

2.1 Core set

Box 1 presents the American College of Rheumatology (ACR) core set for RA. In summary, this includes: three VAS (the doctor and patient global assessment of disease activity and patient perception of pain), two joint counts (the number of tender joints and the number of swollen joints assessed by the physician), one laboratory measure (ESR or CRP), a measure for function (usually the HAQ), and a measure for damage in trials of at least 1 year's duration.

Box 1 American College of Rheumatology (ACR) core set

- Tender joint count
- Swollen joint count
- Patient pain assessment
- Patient global assessment
- Doctor global assessment
- Function
- Acute phase reactant
- Radiographic analysis

Important patient-reported outcomes not included in the core set are related to fatigue and sleep. These are important complaints and might therefore yield additional information. Several instruments to assess fatigue in detail are available, but also a simple VAS on the level of fatigue can already provide sufficient information. Furthermore, to obtain a more complete picture of the disease impact on the lives of rheumatoid arthritis patients, composite patient-reported outcome measures like the RA Impact of Disease (RAID) instrument should be considered in future trial design (Gossec et al, 2011).

Joint counts have always been the backbone of RA disease activity evaluation. There are several joint counts in use (table 1). These differ in the number of joints assessed. Joint counts range from 28 to 74 for swelling, and from 28 to 76 for tenderness. Some scores give a weight to the abnormality and others just score absence or

presence. Moreover, most joint counts assess the number of tender and swollen joints independently, but few scores combine tenderness and swelling. These last scores are not popular. On a group level, reduced joint counts with 28 joints perform as well as more extensive joint counts, and giving weight to the level of tenderness or swelling does not improve the performance of a score. However, the 28-joint counts do not include the feet and this might be inappropriate in clinical practice in individual patients. The most commonly used joint counts will be described in more detail.

Table 1 Joint counts in rheumatology

Joint	74/76 joints	66/68 joints swelling/tenderness	Ritchie articular index (53 joints) tenderness	44 joints swelling	28 joints swelling tenderness
Temporomandibular	+	+	+ [†]		
Sternoclavicular	+	+	+ [†]	+	
Acromioclavicular	+	+	+ [†]	+	
Shoulder	+	+	+	+	+
Elbow	+	+	+	+	+
Wrist	+	+	+	+	+
MCP	+	+	+ [‡]	+	+
PIP (hands)	+	+	+ [‡]	+	+
DIP (hands)	+	+			
Hip	+*	+*	+		
Knee	+	+	+	+	+
Ankle	+	+	+	+	
Talocalcaneal			+		
Tarsus	+	+	+		
MTP	+	+	+ [‡]	+	
PIP (feet)	+	+			
DIP (feet)	+				

*Hip joints are not assessed for swelling.

†Both sides calculated as a single unit.

‡Each group of joints from each side calculated as a single unit.

DIP, distal interphalangeal; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

The Ritchie articular index (figure 3A) is a weighted joint score based on tenderness. All joints are assessed separately. However, the proximal interphalangeal (PIP) joints of each hand, the metacarpophalangeal (MCP) joints of each hand, the metatarsophalangeal (MTP) joints of each foot, the temporomandibular joints, the sternoclavicular joints, and acromioclavicular joints are calculated as a single unit. The highest score for a

single joint gives the score for the group. The joints are graded for tenderness on a 0–3 scale, with 0 = no tenderness, 1 = pain on pressure, 2 = pain and winced, and 3 = winced and withdrew.

The 68-tender joint count is not graded, resulting in a range of 0 to 68.

The 28-joint count excludes mainly the ankles and feet and is again not graded, with a range from 0–28 (figure 3B).

For the assessment of swelling the following joint counts are widely used: the 66-, 44- (figure 3C) and 28-joint counts. All are ungraded and range from 0–66, 0–44, and 0–28, respectively.

Figure 3 Commonly used joint counts.

2.2 Composite measures

For the assessment of disease activity in RA several composite measures have been developed. A widely used composite disease activity score is the **DAS** or one of its modifications. The original DAS comprises *four* variables, including the Ritchie articular index, the 44-swollen joint count, ESR, and patient global assessment of wellbeing (box 2) (*Van der Heijde et al, 1993). The VAS on global wellbeing can either be omitted, resulting in a DAS based on *three* variables, or is frequently replaced by the patient global assessment of disease activity. As these two VAS are closely linked, results with either of the two VAS are comparable. In the DAS with three variables a constant correction factor is included to ensure comparability between DAS4 and DAS3 (on a group level). The multiplication factors in the formulae are derived statistically to obtain the most informative combination of the assessments.

Box 2 DAS formulas

- **DAS (four variables):** $0.54 \times v(\text{Ritchie}) + 0.065 \times (\text{SJC44}) + 0.33 \times \ln(\text{ESR}) + 0.0072 \times (\text{general health})$
- **DAS (three variables):** $0.54 \times v(\text{Ritchie}) + 0.065 \times (\text{SJC44}) + 0.33 \times \ln(\text{ESR}) + 0.22$
- **DAS-CRP (four variables):** $0.54 \times v(\text{Ritchie}) + 0.065 \times (\text{SJC44}) + 0.17 \times \ln(\text{CRP} + 1) + 0.0072 \times (\text{general health}) + 0.45$
- **DAS-CRP (three variables):** $0.54 \times v(\text{Ritchie}) + 0.065 \times (\text{SJC44}) + 0.17 \times \ln(\text{CRP}+1) + 0.65$

CRP, C reactive protein (mg/L); DAS, Disease Activity Score; ESR, erythrocyte sedimentation rate; ln, natural logarithm; SJC44, 44-swollen-joint count.

At a later stage the **DAS28** was developed to replace the Ritchie articular index and the 44-swollen-joint count with the more feasible 28-joint count for both tenderness and swelling (box 3) (*Prevoo et al, 1995). In general, the values for the DAS28 are somewhat higher than the values of the DAS. This can also be seen on the cut-off levels for remission and low disease activity (see below).

Box 3 DAS28 formulas

- **DAS28 (four variables):** $0.56 \times v(\text{TJC28}) + 0.28 \times v(\text{SJC28}) + 0.70 \times \ln(\text{ESR}) + 0.014 \times (\text{general health})$
- **DAS28 (three variables):** $[0.56 \times v(\text{TJC28}) + 0.28 \times v(\text{SJC28}) + 0.70 \times \ln(\text{ESR})] \times 1.08 + 0.16$
- **DAS28-CRP (four variables):** $0.56 \times v(\text{TJC28}) + 0.28 \times v(\text{SJC28}) + 0.014 \times \text{GH} + 0.36 \times \ln(\text{CRP} + 1) + 0.96$
- **DAS28-CRP (three variables):** $[0.56 \times v(\text{TJC28}) + 0.28 \times v(\text{SJC28}) + 0.36 \times \ln(\text{CRP}+1)] \times 1.1 + 1.15$

CRP, C reactive protein (mg/L); DAS, Disease Activity Score; ESR, erythrocyte sedimentation rate; ln, natural logarithm; GH, general health; SJC28, 28-swollen-joint count; TJC28, 28-tender-joint count.

Formulas for DAS and DAS28 using CRP instead of ESR are available (box 2 and 3). The DAS28 CRP was found to be related to radiographic progression and function; however, this was less pronounced as was demonstrated for the DAS28 ESR and the two measures are not exchangeable (Wells et al, 2009). Also other studies showed that DAS/DAS28 with ESR versus DAS28 with CRP do not behave similarly. At the individual level DAS28 CRP is often lower than DAS28 ESR, particularly in females and patients with long disease duration. Therefore, switching between different types of DAS scores in daily clinical practice should be avoided. An online DAS/DAS28 calculator is available at: <http://www.das28.nl/das28/DAScalculators/dasculators.html>.

In recent years two new composite scores have been published summing five variables from the ACR core set without transformation and without weighting (box 4). However, owing to the differences in range of the various variables there is an implicit weighting in these scores.

Box 4 SDAI and CDAI formulas

- **SDAI (five variables):** SJC28 + TJC28 + Patient global health (VAS; 0–10) + Physician global (VAS; 0–10) + CRP(mg/dL)
- **CDAI (four variables):** SJC28 + TJC28 + Patient global health (VAS; 0–10) + Physician global (VAS; 0–10)

CDAI, Clinical Disease Activity Index; CRP, C reactive protein; SDAI, Simplified Disease Activity Index; SJC28, 28-swollen joint count; TJC28, 28-tender joint count; VAS, visual analogue scale.

The **Simplified Disease Activity Index (SDAI)** is the sum of the 28-swollen joint count, the 28-tender joint count, and the patient and investigator global assessments of disease activity on a 10 cm VAS and CRP in mg/dL (*Aletaha et al, 2005). The **Clinical Disease Activity Index (CDAI)** is a modification of the SDAI without the laboratory parameter CRP to allow immediate clinical assessment.

Finally, at the individual level, it is important to highlight that the doctor should be critical about the result of any composite score (as for any type of assessment). For example, in patients with chronically elevated acute-phase reactants not related to RA, the disease activity may be overestimated by the RA-unrelated high CRP/ESR value, and in patients with RA and fibromyalgia disease activity may also be overestimated if fibromyalgia is contributing to patient global assessment and level of tenderness in the joints.

2.3 Response criteria

There are two widely applied types of response criteria for RA: the ACR response criteria and the European League Against Rheumatism (EULAR) response criteria (*Felson et al, 1995; *van Gestel et al, 1996). The **ACR criteria** (box 5) are based on the variables included in the core set. These criteria are referred to as the ACR20, ACR50 and ACR70 response criteria, depending on the required percentage of improvement. A response in both tender and swollen joint counts is obligatory; in addition, three out of the five remaining variables should show a response.

Box 5 ACR improvement criteria

≥20% (ACR20), ≥50% (ACR50) and ≥70% (ACR70) improvement in:

- Tender joint count
- Swollen joint count

and ≥20% (ACR20), ≥50% (ACR50) and ≥70% (ACR70) improvement in three of the following:

- Patient pain
- Patient global
- Assessor global
- Disability
- Acute phase response (ESR/CRP)

ACR, American College of Rheumatology; CRP, C reactive protein; ESR, erythrocyte sedimentation rate.

The **EULAR response criteria** are based on the DAS or on the DAS28 (tables 2 and 3). EULAR response criteria are defined as ‘no’, ‘moderate’ or ‘good’ response. The ACR response criteria are based on a percentage change only, in contrast to the EULAR criteria, which are based on an absolute improvement and the level of disease activity achieved.

Table 2 EULAR response criteria

DAS at end point	Improvement in DAS from baseline		
	>1.2	>0.6 and ≤1.2	≤0.6
≤2.4	Good	Moderate	None
>2.4 and ≤3.7	Moderate	Moderate	None
>3.7	Moderate	None	None

DAS remission <1.6. DAS, Disease Activity Score.

Table 3 EULAR response criteria

DAS28 at end point	Improvement in DAS28 from baseline		
	>1.2	>0.6 and ≤1.2	≤0.6
≤3.2	Good	Moderate	None
>3.2 and ≤5.1	Moderate	Moderate	None
>5.1	Moderate	None	None

DAS28 remission <2.6. DAS28, 28-joint Disease Activity Score.

2.4 Remission, low disease activity

In addition to response criteria, cut-off points to define if a patient is in (clinical) remission or in a state of low disease activity have been developed for the various composite measures (table 4). These measures are becoming more important because they are used as the current treatment goal.

Table 4 Cut-off values for various composite measures

Disease activity	DAS	DAS28	SDAI	CDAI
High	>3.7	>5.1	>26	>22
Moderate	≤3.7	≤5.1	≤26	≤22
Low	≤2.4	≤3.2	≤11	≤10
Remission	<1.6	<2.6	≤3.3	≤2.8

CDAI, Clinical Disease Activity Index; DAS, Disease Activity Score; DAS28, 28-joint Disease Activity Score; SDAI, Simplified Disease Activity Index.

Remission is now included as an endpoint for clinical trials and observational studies and is also a major therapeutic target in clinical practice. Remission should be understood as a near complete suppression of

disease activity or absence of any discernible disease activity. Due to limitations in the various definitions of remission and recognizing its importance as a crucial goal in current RA management, ACR and EULAR set up a task force to redefine the concept and published a new definition in 2011 (box 6) (*Felson et al, 2011). Since in the clinical setting CRP is sometimes not available at every visit, an alternative definition of remission without CRP was proposed for daily practice.

Box 6 ACR/EULAR 2011 provisional definition of RA remission

For clinical trials:

Boolean-based definition

At any time point, patient must satisfy all of the following:

- Tender joint count ≤ 1
- Swollen joint count ≤ 1
- Patient global assessment ≤ 1 (0–10 scale)
- C reactive protein ≤ 1 mg/dL

Index-based definition

- Simplified Disease Activity Index score ≤ 3.3

For clinical practice:

Boolean-based definition

At any time point, patient must satisfy all of the following:

- Tender joint count ≤ 1
- Swollen joint count ≤ 1
- Patient global assessment ≤ 1 (0–10 scale)

Index-based definition

- Clinical Disease Activity Index score ≤ 2.8

ACR, American College of Rheumatology; EULAR, European League Against Rheumatism; RA, rheumatoid arthritis.

2.5 Frequency of monitoring

The minimum frequency of monitoring for implementing effective treatment during the active phases of the disease is 3-monthly. When a patient is in persistent remission, this can be reduced to 6-monthly follow-ups.

2.6 Imaging assessment

2.6.1 Conventional radiographs

Radiographic imaging is the imaging method most widely used in the diagnosis of RA and to follow the course of the disease and effectiveness of treatment (*Van der Heijde et al, 2004).

A series of radiographs comprises the simplest and cheapest permanent record of the cumulative joint damage caused by the disease. Damage assessed on radiographs is a direct consequence of disease activity, as well as other destructive pathophysiological processes. There is also a close relationship between radiographic damage and other outcome measures, such as functional ability and work disability. As damage is largely

irreversible, structural damage on radiographs is a reflection of cumulative disease activity in the past.

However, more and more reports have shown that repair of damage is possible to some extent. Repair occurs most frequently in patients receiving biologic treatment and in joints with improved swelling (Lukas et al, 2010). More information is needed on how frequently this repair does occur, the significance of the repair (e.g., is a joint with repair functioning better than a joint without signs of repair?), how long it takes to see repair, and how repair may be best assessed.

2.6.1.1 Which abnormalities?

Many abnormalities in joints can be detected on plain films in RA (figure 4). These include soft tissue swelling and proliferation, juxta-articular and diffuse osteoporosis, marginal bony erosions, subchondral cysts, joint space narrowing (JSN) as a consequence of cartilage loss, subluxation and misalignment, ankylosis, sclerosis, and osteophytes in severely damaged joints. Both erosions and JSN are the most specific features in RA and can be assessed reliably. Moreover, they give additive information. Erosions are present in about 80% of patients in most longitudinal cohorts. The majority of patients develop the first erosions within the first year after onset. Erosions both in hands and feet are common early features, often appearing in the feet earlier than in the hands. The wrist is the most common joint for early JSN.

Figure 4 Structural damage in rheumatoid arthritis (arrows showing erosions, lines showing joint space narrowing).

2.6.1.2 Which joints?

Films of the hands and feet are sufficient for both diagnostic and evaluation purposes. Hands and feet are the joints affected in most patients, abnormalities on radiographs can be seen more easily in small joints than in large joints, and structural damage in small joints reflects damage in large joints. Already in the mid-1980s, Scott et al showed in a cross-sectional group of patients that there is a good correlation between damage seen in the hands and that in other joints. This has been confirmed in an inception cohort of middle-aged women, followed up for 12 years. The correlation between damage in the hands and feet and that in large joints was as high as 0.76 (Drossaers-Bakker KW et al, 2000). This indicates that films of hands and feet are satisfactory to follow the course of disease and to monitor efficacy of treatment in individual patients. Films of large joints should only be taken if clinically indicated. An essential finding in that same study was that no patients without erosions in hands and feet showed erosive changes in the large joints. Although RA is a symmetrical disease, imaging of only one hand and one foot would result in considerable loss of information.

2.6.2 Scoring methods: general introduction

The information from radiographs is especially useful if it is quantified. Several scoring methods, which will be discussed later in this chapter, are available.

Selection of the most appropriate scoring method is largely dependent on the setting in which it will be applied. For example, in clinical practice and large cohort studies, feasibility is of major importance, while in clinical trials sensitivity to change drives the selection of a method. Selection of the scoring method also depends on whether data are needed to show progression over a short or a long follow-up period, or are important at a single point in time.

This chapter describes the methods that are used most frequently in research and clinical practice. For a historical overview of all published scoring methods we refer to the literature. Methods applying a global score, and based mainly on the Larsen method, are presented below. This is followed by the presentation of more detailed scoring methods, based mainly on the Sharp method. Table 5 summarises the various characteristics of the scoring methods.

Global score each joint

- ➡ Larsen score (global score combining erosion/JSN; also large joints)
- ➡ modified Larsen score (simplification with better resolution)
- ➡ Scott modification Larsen score (other grading)

Detailed score each joint

- ➡ Ratingen score (only % surface erosion of each joint)
- ➡ Sharp's method (score erosions, JSN separately; only hands)
- ➡ Genant's modification of Sharp's method (can include the feet)
- ➡ Van der Heijde's modification of Sharp's method (also the feet)
- ➡ Simple Erosion Narrowing Score (SENS) (same joints as vd Heijde)

2.6.3 Global assessment for each joint**2.6.3.1 Larsen score (hands and feet +/- large joints)**

The Larsen score applies a grade from 0 to 5 to individual joints (Larsen et al, 1977). This is the only method that can be applied to both large and small joints and a reference atlas with the grades for the various joints is available. The scoring is mainly a combination of erosions and JSN, resulting in a global grade. The original Larsen scoring method includes soft tissue swelling and juxta-articular osteoporosis in grade 1. Only from grade 2 onwards are definite abnormalities, such as erosions, present. Grade 5 represents mutilating abnormality. Several modifications of this scoring system have been published, the most important modification being for use in longitudinal studies. Most studies include only the joints of the hands, wrists and feet. The information in table 5 is based on the original method applied to hands, wrists and feet. In the original Larsen score, the wrist is evaluated as a single joint. In total 32 joints are scored (0-5) and this leads to a scoring range for hands and feet from 0 to 160. The modification by Larsen has amended both the sites to be evaluated as well as the grading, for a more uniform evaluation in studies (Larsen et al, 1995). Most striking is the deletion of soft tissue swelling and osteoporosis for grade 1. Now erosions <1 mm and slight JSN are graded as 1. The number of areas in both hands and feet has been changed. The interphalangeal (IP) and MCP joints of the thumb are no longer included, and neither are the IP nor metatarsophalangeal (MTP) joints of the big toe. In this modification the wrist is scored in quadrants. Therefore, the number of joints assessed remains as 32.

Table 5 Comparison of radiographic scoring methods for rheumatoid arthritis

	Larsen method	Scott modification of Larsen method	Ratigen method	Sharp method	Genant modification of Sharp method	van der Heijde modification of Sharp method	Simple Erosion Narrowing Score (SENS)
<i>Films</i>							
Hands	X	X	X	X	X	X	X
Feet	X	X	–	–	X	X	X
Large joints	X*	–	–	–	–	–	–
<i>Joints included</i>							
PIP/IP	X	X	X	X	X	X	X
MCP	X	X	X	X	X	X	X
Wrist	X	X	X	X	X	X	X
MTP	X	X	–	–	X	X	X
IP1	X	X	–	–	X	X	X
<i>Features scored</i>							
Erosions	–	–	X	X	X	X	X

Misalignment	–	–	–	–	–	X	X
Global	X	X	–	–	–	–	–
<i>Number of joints per hand/foot scored for</i>							
Erosions	–	–	19	17	14	22	22
JSN	–	–	–	18	13	21	21
Misalignment	–	–	–	–	–	‡	‡
Global	16	16	–	–	–	–	–
<i>Range per joint</i>							
Erosions	–	–	0–5	0–5	0–3+ [†]	0–5/0–10 [§]	0–1
JSN	–	–	–	0–4	0–4 [†]	0–4	0–1
Malalignment	–	–	–	–	–	‡	‡
Global	0–5	0–5	–	–	–	–	–
Total	0–160	0–200	0–190	0–314	0–202	0–448	0–86

*Large joints are assessed separately; the remaining information in this table is based on hands and feet.

†Scored per 0.5.

‡Combined with the JSN score.

§Erosions for hands 0–5, for feet 0–10.

IP, interphalangeal; JSN, joint space narrowing; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

2.6.3.2 Scott modification of Larsen's method (hands and feet)

The modification by Scott et al in 1986 is frequently used when the 'Larsen' method is applied. The authors redefined the grading and applied it to the same 32 joints as in the original Larsen method. Moreover, the

wrist is scored as a single joint, but is weighted by a factor of 5 to obtain the total score (0-25). This produces a range for hands and feet of 0–200 (total score of 2 wrists (0-25) and 30 other joints (0-5)).

2.6.3.3 Ratingen score (hands and wrists only)

In this modification of the Larsen score, the grading is entirely based on the surface area of the joints destroyed by erosions (Rau et al, 1998). This is graded from 0 to 5: grade 1, <20%; grade 2, 21–40%; up to grade 5, >80% destroyed. In total 38 joints of the hands including the wrists are scored (0-5), resulting in a range of 0–190.

2.6.4 Detailed scoring methods

2.6.4.1 Sharp's method (hands and feet)

Sharp's method was the first published description of a detailed scoring system for erosions and JSN separately for joints in the hands and wrists. The Sharp method used at present is the modification described in 1985 (Sharp et al, 1985). This reduced the number of joints scored from originally 27 for both erosions and JSN to 17 areas for erosions and 18 for JSN for each hand, which simplified the scoring.

Moreover, the method was developed and validated for scoring the joints of the hands, but nowadays the same methodology is also applied to the joints of the feet (cfr infra: Genant and van der Heijde modification). **Erosions** are scored from 0 to 5 for each joint. Scores are applied as: 0, no erosion; 1, one discrete erosion or involvement of <21% of the joint area by erosion; 2, two discrete erosions or involvement of 21% through 40% of the joint; 3, three discrete erosions or involvement of 41% through 60% of the joint; 4, four discrete erosions or involvement of 61% through 80% of the joint; 5, extensive destruction involving >80%. **JSN** is scored on a 0–4 scale, representing focal narrowing (score 1), joint space loss of <50% (score 2), joint space loss of >50% (score 3), and complete joint space loss or ankylosis (score 4). Subluxation or luxation is not included in the score. The erosion score and the JSN score can be used separately but are usually summed to get the total score.

2.6.4.2 Genant's modification of Sharp's method (hands and feet)

A modification of the Sharp method is described by Genant, which extended the scale for progression from a six-point scale (0 to 5) to an eight-point scale with 0.5 increments from 0 to 3+ for erosions, and from a five-point scale (0 to 4) to a nine-point scale with 0.5 increments from 0 to 4 for JSN (Genant, 1983). This score is applied in 14 joints of each hand and wrist for erosions and in 13 joints for JSN. This results in a total score range of 0–202. Frequently, this is normalised to a 200-point scale.

2.6.4.3 van der Heijde's modification of Sharp's method (hands and feet)

The main modification by van der Heijde was the addition of six joints for each foot to the scoring system (see figure 5) (van der Heijde, 1999). Moreover, in the hands one site for erosions and three sites for JSN were deleted from the scoring areas as compared with the Sharp's method as described in 1985, leaving 16 sites for erosions and 15 for JSN for each hand. The scoring of **erosions** in the hands remained the same with a range of 0–5 for each joint. However, for the scoring of erosions in the feet the scoring range was expanded to 10 per joint, with a maximum of five for the metatarsal and phalangeal site of the joint. Another major difference is that subluxation and luxation (misalignment) are integrated in the grading of JSN. **JSN** is scored on a 0–4 scale, with the same grading as described for the Sharp method. But in this modification a score of 3 can also be applied in the case of subluxation of a joint and a score of 4 in the case of complete luxation. These features are mostly scored in MCP joints and MTP joints. In total 2x6 sites in the feet (maximum 10) and 2x16 sites in the hands (maximum 5) are scored for erosions (range 0-280). For JSN 2x6 sites in the feet and 2x15 sites in the hands ((maximum 4) are scored (range 0-168). The scoring range for the total score is 0–448 (erosion score + JSN score).

2.6.4.4 Simple Erosion Narrowing Score (hands and feet)

The Simple Erosion Narrowing Score (SENS) is based on the same joints included in the van der Heijde modification of Sharp's method for hands and feet (figure 5). Instead of scoring the joints for erosions and JSN, this is a simple counting of the number of eroded joints and the number of narrowed joints. A score of 1 is applied if a site is eroded and also for each narrowed site. In total 16 joints per hand are scored for erosions and 15 for JSN, and six joints per foot for both erosions and JSN, leading to a scoring range from 0 to 86. A score form that can be used for the SENS is available (figure 5).

Figure 5 Scoring sheets for radiographs (*Simple Erosion Narrowing Score (SENS) method*). JSN, joint space narrowing.

2.6.5 Assessment of structural damage in clinical practice

Several scoring methods are available for use in clinical trials. Most widely used are the Larsen and Sharp methods with several modifications. However, they are not very practical for use in clinical practice. Therefore, the above-described SENS method was developed and tested. The method is easy to learn and easy to apply in clinical practice and takes only a few minutes. An increase of 1 in the score (equivalent to a newly eroded or narrowed joint) can be considered as progressive disease. It is recommended that annual radiographs of hands and feet are taken, and also for patients in clinical remission. If patients remain in persistent remission and do not show progression of structural damage, the frequency of taking radiographs can be reduced.

2.7 Magnetic resonance imaging

Conventional radiography, although the most widely used imaging method in RA, has limitations. It is not sensitive for detecting early disease manifestations such as soft tissue inflammation—that is, it cannot be used to assess current disease activity and it does not visualise the earliest stages of bone erosion. In contrast, magnetic resonance imaging (MRI) and ultrasonography (US) allow direct visualisation of early inflammatory as well as early destructive joint changes in RA (McQueen et al, 2007; Østergaard et al, 2008).

2.7.1 Which abnormalities?

MRI provides multiplanar tomographic imaging with unprecedented soft tissue contrast, without the use of ionising radiation, and allows assessment of all the structures involved in arthritic disease—that is, synovial

membrane, intra- and extra-articular fluid collections, cartilage, bone, ligaments, tendons, and tendon sheaths. It has been shown to be more sensitive than clinical examination and radiography for detection of inflammatory and destructive joint changes in early RA. MRI and histopathological signs of synovial inflammation are closely correlated and in a study of MCP joints in patients with early and established RA, mini-arthroscopy confirmed the presence of bone pathology in all joints with MRI bone erosions and histological and macroscopic synovitis in all joints with MRI synovitis (Ostendorf et al, 2001).

A high level of agreement between MRI and computed tomography (CT) -the 'gold standard' reference for detection of bony destruction- for detection of bone erosions in RA wrists and MCP joints (concordance at 87–90% of sites) documents that MRI erosions represent true bone damage (Perry et al, 2005).

2.7.2 Which joints and how to acquire images?

Most MRI studies in RA have investigated knee, wrist or finger joints. Reports on other peripheral joints are few in number and not essentially different. The few studies available on MRI of the feet do not suggest any advantage in imaging feet rather than wrists and hands. Although only one formal comparison with follow-up of other joints exists, *MRI of unilateral MCP joints and wrist joints* are most commonly recommended, while MRI of other joints should only be obtained if specifically clinically indicated.

Compared with radiography, MRI offers clear advantages, but also disadvantages such as increased cost and lower availability. However, MRI costs represent only a fraction of the total expense incurred in the management of patients with RA, when the costs of treatment of RA with biological agents or of the indirect costs of sick leave/early retirement are considered. Nevertheless, reducing the cost of MRI would be advantageous and would encourage clinicians to use MRI more often. Dedicated extremity MRI units are being used increasingly because they offer improved patient comfort at lower cost than conventional whole-body MRI units. The best of the dedicated low-field MRI units provide similar information on erosions and synovitis as conventional high-field whole-body MRI. However, performance characteristics of different machines differ widely, emphasising the need for careful testing.

Optimal MRI assessment of synovitis requires the use of intravenous gadolinium contrast, while assessment of bone oedema and erosions does not. Thus, for assessment of synovitis, bone oedema and erosions, a *pre- and post-contrast T1-weighted sequence in two planes* plus a *T2-weighted fat-saturated or short tau inversion recovery (STIR) sequence* is recommended.

2.7.3 Methods for assessment

Numerous pathologies can be visualised by MRI, but systematic methods for assessing RA activity and damage have focused on synovitis, bone marrow oedema and bone erosions. MRI allows quantitative (contrast uptake ('enhancement') rate after intravenous injection (only synovitis) or synovial membrane volume) as well as less

detailed (qualitative: presence/absence; semi-quantitative: scoring) evaluation of synovitis and bone erosions. In clinical practice a qualitative description of the images is used, whereas the more laborious quantitative assessments are used for research purposes.

The most commonly used assessment method is the Outcome Measures in Rheumatology (OMERACT) RA MRI scoring system (**RAMRIS**), which involves semi-quantitative assessment of synovitis, bone erosions, and bone oedema in RA hands and wrists. Recently also a RAMRIS JSN scoring system (joint space narrowing) was developed and validated (Glinatsi et al, 2015). In addition, scoring methods for tenosynovitis are currently under validation. The RAMRIS (box 7) was developed and validated through interactive multicentre studies through OMERACT and EULAR collaborations. A consensus on MRI definitions of important joint pathologies and a 'core set' of basic MRI sequences has also been presented (box 7).

RAMRIS erosion scores are closely correlated with erosion volumes estimated by MRI and CT, and good intra- and inter-reader reliability and a high level of sensitivity to change have been reported. This supports the suitability of RAMRIS for use in monitoring activity and damage in RA, after proper training and calibration of readers. A EULAR–OMERACT RA MRI reference image atlas has been developed, providing an easy-to-use tool for standardised RAMRIS scoring of MR images for RA activity and damage by comparison with standard reference images (*Østergaard et al, 2005).

Box 7 OMERACT MRI in rheumatoid arthritis (RA) group recommendations of a ‘core set’ of basic MRI sequences, MRI definitions of important RA joint pathologies and an RA MRI scoring system (OMERACT 2002 RAMRIS)

‘Core set’ of basic MRI sequences

It is suggested that future MRI studies, which intend to assess inflammatory as well as destructive changes in RA joints, should at least include the following:

- Imaging in two planes* with T1-weighted images before and after IV gadolinium contrast†
- A T2-weighted fat saturated sequence or, if the latter is not available, a short tau inversion recovery (STIR) sequence

**Imaging in two planes can be acquired by obtaining a two dimensional sequence in two planes, or a three dimensional sequence with isometric voxels in one plane allowing reconstruction in other planes.*

†IV gadolinium injection is not essential if destructive changes alone (bone erosions) are considered important.

Definitions of important RA joint pathologies

- Synovitis: An area in the synovial compartment that shows above-normal post-gadolinium enhancement* of a thickness greater than the width of the normal synovium
- MRI bone erosion: A sharply marginated bone lesion, with correct juxta-articular localisation and typical signal characteristics†, which is visible in two planes with a cortical break seen in at least one plane‡
- MRI bone oedema: A lesion§ within the trabecular bone, with ill-defined margins and signal characteristics consistent with increased water content

**Enhancement (signal intensity increase) is judged by comparison of T1-weighted images obtained before and after IV gadolinium contrast.*

†On T1-weighted images: loss of normal low signal intensity of cortical bone and loss of normal high signal intensity of trabecular bone. Quick post-gadolinium enhancement suggests the presence of active, hypervascularised pannus tissue in the erosion.

‡Other focal bone lesions, including metastases, must obviously be considered, but are generally distinguishable with associated imaging and clinical findings.

§May occur alone or surrounding an erosion or other bone abnormalities; high signal intensity on T2-weighted fat-saturated and STIR images and low signal intensity on T1-weighted images.

Scoring system

- Synovitis: Synovitis is assessed in three wrist regions (the distal radioulnar joint; the radiocarpal joint; the intercarpal and carpometacarpophalangeal joints) and in each metacarpophalangeal (MCP) joint. The first carpometacarpophalangeal joint and the first MCP joint are not scored. Synovitis is scored from 0 to 3.
- Bone erosions: Each bone (wrists: carpal bones, distal radius, distal ulna, metacarpal bases; MCP joints: metacarpal heads, phalangeal bases) is scored separately from 0 to 10.
- Bone oedema: Each bone is scored separately (as for erosions) from 0 to 3.
- Sum scores: Sum scores of synovitis, erosion and oedema, respectively, are calculated by summation of individual joint scores, as a total sum or separately in the evaluated wrist and 2nd–5th MCP joints. For synovitis, the possible range of sum scores of unilateral 2nd–5th MCP joints, wrist joint and both are 0–12, 0–9 and 0–21, respectively. Corresponding values for bone erosion are 0–80, 0–150 and 0–230, while for bone oedema the values are 0–24, 0–45 and 0–69.

IV, intravenous; MRI, magnetic resonance imaging; OMERACT, Outcome Measures in Rheumatology; RAMRIS, Rheumatoid Arthritis Magnetic Resonance Imaging Scoring system.

2.7.4 Predicting and monitoring disease activity and damage: implications for clinical practice

MRI synovitis can be assessed with high reproducibility and is sensitive to change. In patients with clinical remission, MRI synovitis is common and has been shown to predict subsequent erosive progression (Bøyesen et al, 2010). MRI bone oedema is an independent predictor of subsequent radiographic progression in early RA (figure 6) and MRI measured inflammation is sensitive to change during treatment (Haavardsholm et al, 2008 and 2009; Hetland et al 2009) . MRI has also been shown to detect inflammation in RA patients experiencing progression in joint damage despite clinical remission (Brown et al, 2008). This supports the use of MRI detected inflammation for predicting the disease course, monitoring response to therapy, and defining remission in selected cases.

Figure 6 Bone marrow oedema in early rheumatoid arthritis patients (in the radius and hamate) is an independent predictor of subsequent radiographic joint damage (bone marrow oedema can only be visualised by magnetic resonance imaging).

MRI may also be used in early RA patients with normal radiographs to determine whether a patient has erosions. However, care should be taken (including requiring erosions to be visible in two planes) to avoid overestimation of erosive disease, and proper training is essential since erosion-like changes may be seen in patients without RA. Several studies have shown that MRI is more sensitive than radiography for monitoring erosive progression—that is, damage in the individual joint regions. MRI of a few joints is also reported to be more sensitive than radiography of many joints, using the Sharp/van der Heijde method, which is generally considered the most sensitive radiographic method. In established RA, RAMRIS scoring of unilateral wrist and MCP joints was more sensitive to change than Sharp/van der Heijde radiographic scoring of bilateral hands,

wrist and forefeet. Early MRI erosion progression could therefore be considered as a valid measure of structural damage that could substantially decrease sample size and study duration if used as structural damage end point in RA clinical trials (Baker et al, 2016).

2.8 Ultrasonography

US has several advantages. It has low running costs, is patient friendly, relatively easily accessible, and is interactive with the patient. The examination involves no ionising radiation, is multiplanar and visualises joint structures in real time. A Doppler examination provides haemodynamic information on the examined tissue. US enables quick examination of several joints in different body regions during one session and is easy to repeat, making follow-up examinations convenient and comfortable for the patient. However, the assessment of joints with US is limited as ultrasound cannot penetrate bone, and because of intra-machine and inter-reader variability and the lack of systems for assessment of activity and damage that have been tested longitudinally in follow-up studies.

2.8.1 Which abnormalities?

US can visualise inflammatory as well as destructive RA changes. It allows assessment of synovitis, both by detecting thickening of the synovial membrane of inflamed joints, bursae or tendon sheaths by grey scale (B-mode) US and by disclosing, and potentially quantifying, increased synovial blood flow using Doppler techniques. At knee and hip joints, the power Doppler signal has been found to correlate well with histological assessment of synovial membrane microvascular density. Although no similar data are available for small joints, there is strong agreement between US and MRI for the detection of synovial inflammation. High-frequency probes are required for satisfactory examination of the small joints of the hands and feet. US can also detect fluid in joints, bursae and tendon sheaths and may be used to evaluate the integrity of tendons and ligaments, as well as for imaging of enthesal inflammation.

It has been reported that US is more sensitive for visualising bone erosions in RA finger joints than conventional radiography. It is comparable to MRI in this respect, but inferior to MRI for detection and follow-up of erosions in wrists. Its sensitivity for detecting bone erosions is markedly site-dependent (high in easily accessible joints but low in anatomically complicated joints), owing to the fact that US cannot penetrate bone. Where accessibility is optimal, US registration of bone erosions shows high agreement with assessments by MRI and CT.

2.8.2 Which joints?

The exact number and localisation of joints that should be examined by US to obtain the best monitoring of RA has not yet been clarified. Based on cross-sectional data systems, incorporating a reduced number of joints has been suggested but needs further testing.

2.8.3 Methods for assessment

No generally accepted overall system for the assessment of RA activity and damage exists, but important advances have been made recently. In working groups under OMERACT and EULAR banners, definitions of important joint pathologies have been reported and a series of reproducibility studies performed, aiming at international consensus. Even though standardisation and validation is still incomplete, US is widely used in clinical practice in several countries for guiding injections and for investigating joint inflammation.

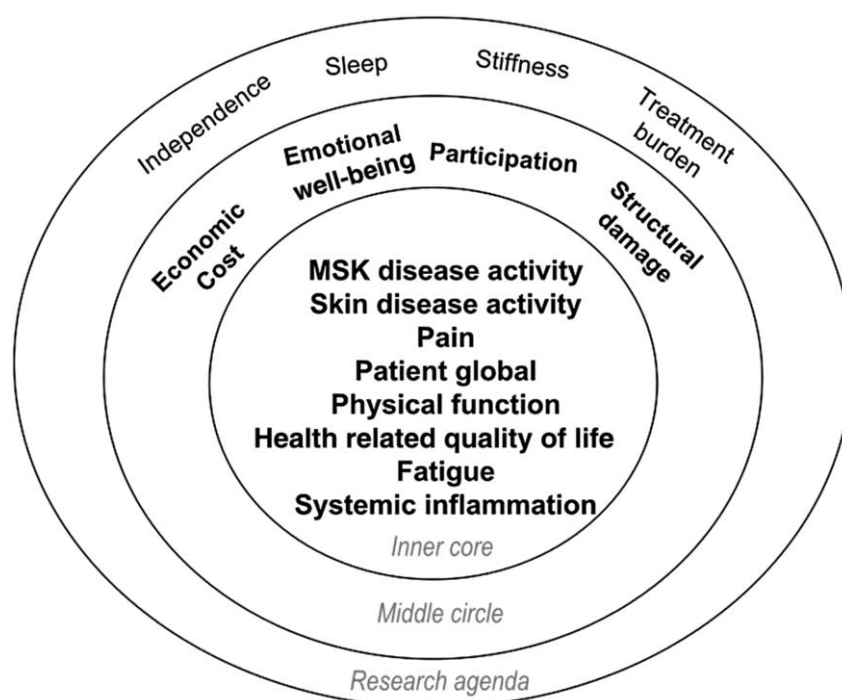

2.8.4 Predicting and monitoring disease activity and damage: implications for clinical practice

US grey scale synovitis of the wrist has been shown to be an independent predictor of subsequent bone erosions (Bøyesen et al, 2011). There is also accumulating evidence that a Power Doppler signal within synovial hypertrophy is associated with subsequent damage of the bone. However, further studies are still needed with regards to the prognostic role of US in RA (Naredo et al, 2005; Taylor et al, 2004; Janta et al, 2016; D'Agostino et al, 2016). US is, on the other hand, a sensitive measure of inflammation and has been shown to be sensitive to change during treatment, thus accentuating its role in disease monitoring of RA patients (Naredo et al, 2008).

3 Psoriatic arthritis

3.1 Core set

The GRAPPA-OMERACT PsA Working group recently updated the core set of outcomes to be measured in psoriatic arthritis (PsA) clinical trials. The updated PsA Core domain set includes: musculoskeletal disease activity (which now includes enthesitis, dactylitis, and spine symptoms in addition to peripheral arthritis) and skin disease activity (including nail disease), pain, patient global assessment, physical function, HRQoL, fatigue and systemic inflammation. Changes compared to the 2006 Core Domain set include moving fatigue and systemic inflammation to the inner circle (to be collected in all trials of PsA) and moving structural damage, participation, and emotional wellbeing to the middle circle (strongly recommended but not feasible to access in all clinical trials). Four new items were also added to the research agenda for further study (stiffness, independence, treatment burden, and sleep) (Orbai et al, 2016).

Figure 7 Psoriatic arthritis core set (Orbai et al, 2016)

In principle, all joint counts applied in RA are also used in PsA. However, as involvement of the distal interphalangeal (DIP) joints is a main characteristic of PsA, these are typically included in joint counts for this disease. Frequently, 68 tender and 66 swollen joints are employed. In some instances these have been extended, with the DIP joints of the feet and the carpometacarpal joints of the hands included to yield a full 78 tender and 76 swollen joint count.

3.2 Assessment tools for psoriatic arthritis

There has been great progress in the assessment of patients with PsA. Several assessment tools have been validated and new tools continue to be developed. A summary of these tools is presented in table 6. Some of these measures will be highlighted below. Further details can be found in the literature (*Mease PJ, 2011).

Table 6 Assessment tools for psoriatic arthritis

Measures	Specific tools
Peripheral joint assessment	Tender/swollen joint count (extended joint counts are preferred)
Axial joint assessment	ASDAS, BASDAI, BASFI, BASMI
PsA composite measures and response criteria	DAS/DAS28, DAPSA, CPDAI, PASDAS, AMDF, PsAJAI, PsARC and ACR response criteria
Skin assessment	PASI, BSA, target lesion, Global
Enthesitis assessment	Mander, MASES, Leeds, Berlin, SPARCC, 4-point
Dactylitis assessment	Leeds, present/absent, acute/chronic
Patient global	VAS (global, skin + joints)
Physician global	VAS (global, skin + joints)
Function/HRQoL	HAQ, SF-36, PsAQoL, DLQI

ACR, American College of Rheumatology; AMDF, Arithmetic Mean of Desirability Functions; ASDAS, Ankylosing Spondylitis Disease Activity Score; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BASFI, Bath Ankylosing Spondylitis Functional Index; BASMI, Bath Ankylosing Spondylitis Metrology Index; BSA, body surface area; CPDAI, Composite Psoriatic Disease Activity Index; DAS, Disease Activity Score; DAPSA, Disease Activity in Psoriatic Arthritis; DLQI, Dermatology Life Quality Index; HAQ, Health Assessment Questionnaire; HRQL, Health Related Quality of Life; MASES, Maastricht Ankylosing Spondylitis Enthesitis Score; PASI, Psoriasis Area and Severity Index; PASDAS, Psoriatic Arthritis Disease Activity Score; PsA, psoriatic arthritis; PsAJAI, Psoriatic Arthritis Joint Activity Index; PsAQoL, Psoriatic Arthritis Quality of Life; PsARC, Psoriatic Arthritis Response Criteria; SF-36, 36-Item Short Form Health Survey; SPARCC, Spondyloarthritis Research Consortium of Canada; VAS, Visual Analogue Scale.

3.3 Composite measures

A summary of composite disease activity scores proposed in psoriatic arthritis and the components of each score are presented in table 7.

Table 7 Summary of Composite Disease Activity Scores proposed in Psoriatic Arthritis

	ACR	DAS/ DAS28/ EULAR	PSARC	DAPSA	cDAPSA	CPDAI	mCPDAI	CPDAI- JED	PsAJAI	PASDAS	ADMDF/ GRACE Index	MDA

ACR, American College of Rheumatology response criteria; AMDF, Arithmetic Mean of Desirability Function; CPDAI, Composite Psoriatic Disease Activity Index; mCPDAI, modified CPDAI; CPDAI-JED, CPDAI joints, entheses, dactylitis; DAPSA, Disease Activity in Psoriatic Arthritis; cDAPSA, clinical version of the DAPSA; DAS, Disease Activity Score; DAS 28, 28-joint Disease Activity Score; EULAR, European League Against Rheumatism response criteria; GRACE Index, GRAppa Composite Exercise Index (GRACE index = [1-AMDF]); HAQ, Health Assessment of Questionnaire; HRQoL, Health related quality of life; MDA, Minimal Disease Activity; PASDAS, Psoriatic Arthritis Disease Activity Score; PGA, Patient Global Assessment; PhGA, Physician Global Assessment; PsAJAI, Psoriatic Arthritis Joint Activity Index; PsARC, Psoriatic Arthritis Response Criteria; TJC/SJC, Tender Joint Count/Swollen Joint Count.

The **DAS** and **DAS28** as described for RA have been widely used in PsA. They have been shown to be useful in polyarticular disease but there are concerns about the validity of their use in the general PsA population, namely in patients with oligoarticular disease, in patients with involvement of the DIP joints of the hands and in patients with predominantly lower limb involvement.

The Disease Activity in PsA (**DAPSA**) score largely assesses the articular component of the disease (box 8). Cut-offs for disease activity states and response criteria according to the DAPSA and the clinical DAPSA (cDAPSA) have been developed. The following DAPSA cut-offs were proposed: for remission, $DAPSA \leq 4$; for low disease activity, $4 < DAPSA \leq 14$; for moderate disease activity, $14 < DAPSA \leq 28$; for high disease activity, $DAPSA > 28$. Derived cDAPSA cut-offs were similar and the investigators arbitrarily proposed to reduce the cDAPSA cut-off between moderate and high disease activity by one point compared with the DAPSA, to account for the putative higher levels of CRP in patients with these levels of disease activity: for remission, $cDAPSA \leq 4$; for low disease activity, $4 < cDAPSA \leq 13$; for moderate disease activity, $13 < cDAPSA \leq 27$; for high disease activity, $cDAPSA > 27$. The following DAPSA response criteria were proposed: minor response, 50% change in DAPSA; moderate response, 75% change; major response, 85% change. Discriminative validity was assessed using Qui-square statistics.

The Composite Psoriatic arthritis Disease Activity Index (**CPDAI**) assesses disease activity in five domains: skin, joint, enthesis, dactylitis and spine; a score of 0 = not involved, 1 = mild, 2 = moderate or 3 = severe involvement, is attributed to each domain based on pre-defined criteria, resulting in a final score from 0–15.

The Psoriatic Arthritis Joint Activity Index (**PsAJAI**) is the weighted sum of scores given in case of a least 30% improvement in each of six measures with weights of 2 given to tender joint count, CRP level, and physician global assessment of disease activity. Weights of 1 are given to the remaining 30% improvement measures, including pain, patient global assessment of disease activity, and HAQ. PsAJAI range is 0–9 with a preliminary definition of response being a PsAJAI ≥ 5 .

Two novel indices were recently proposed, the **Psoriatic Arthritis Disease Activity Score (PASDAS)**, (box 8), developed in analogy to the DAS/ASDAS, and the **Arithmetic Mean of Desirability Functions (AMDF)**, which uses the arithmetic mean of 8 transformed empirically selected variables and arbitrary cut-offs (tender and

swollen joint counts, HAQ, patient VAS for global assessment, patient VAS for skin, patient VAS for joints, psoriasis area and severity index (PASI), and PsA quality-of-life index (PsAQoL)). Further validation and comparative studies are required until a final consensus can be reached about the best measure(s) to use in PsA.

Box 8 Psoriatic arthritis (PsA) composite measures

Disease Activity in PsA (DAPSA) score

SJC66 + TJC68 + Patient global (VAS, 0–10) + Pain (VAS, 0–10) + CRP

PsA Disease Activity Score (PASDAS)

$$0.18 \times \sqrt{\text{Doctor global VAS}} + 0.159 \times \sqrt{\text{Patient global VAS}} - 0.253 \times \sqrt{\text{SF36-PCS}} + 0.101 \ln(\text{SJC66} + 1) + 0.048 \ln(\text{TJC68} + 1) + 0.23 \times \ln(\text{Leeds enthesitis count} + 1) + 0.377 \ln(\text{tender dactylitis count} + 1) + [0.102 \ln(\text{CRP} + 1) + 2] \times 1.5$$

CRP, C reactive protein (mg/dL for DAPSA and mg/L for PASDAS); PSC, physical component scale of SF36; ln, natural logarithm; VAS, visual analogue scale.

3.4 Response criteria

Three response criteria are in use for PsA: the PsA response criteria (**PsARC**), developed specifically for PsA, and **the ACR and EULAR response criteria**, originally developed for RA. To achieve a PsARC response a patient has to achieve two of the following, one of which has to be a joint count and no worsening of any measure: tender or swollen joint count improvement of at least 30% (worsening defined as an increase of at least 30%), patient global improvement by 1 point on a 5-point Likert scale, or doctor global improvement on the same scale (worsening defined as an increase of one point). All three response criteria can discriminate placebo from active treatment in clinical trials. The incidence of an ACR 20 response is typically lower than a PsARC response, although for the PsARC a 30% improvement is required. It has been suggested that this may be because only one of the joint counts needs to have improved and assessments such as acute phase reactants and HAQ are not included. Validation of the current criteria and further development of the PsARC are continuing. Development and validation of response criteria for other composite measures is ongoing.

3.5 Remission, low disease activity

Criteria to define minimal disease activity (**MDA**) have been proposed and validated by Coates et al (2010*). Patients are classified as having MDA if their score is equal to or below the predefined cut-off for five of seven outcome measures: tender joint count ≤ 1 ; swollen joint count ≤ 1 ; PASI ≤ 1 or body surface area ≤ 3 ; patient pain VAS score ≤ 15 (0–100 scale); patient global disease activity VAS score ≤ 20 (0–100 scale); HAQ score ≤ 0.5 ; and tender entheses points ≤ 1 .

3.6 Frequency of monitoring

Little information is available about the optimum frequency of monitoring. However, the guidelines for monitoring clinical disease activity for RA seem to be applicable also to PsA (3-monthly during active disease and reduced to 6-monthly follow-ups if a patient is in remission/MDA).

3.7 Imaging assessment

3.7.1 Conventional radiographs

Radiographic imaging is the most widely used imaging method in PsA. Although there are similarities with RA, there are also major differences in, for example, the type and site of lesions as well as the joints affected. Whereas RA is characterised by mainly osteodestructive lesions, in PsA there are both osteodestructive and osteoproliferative manifestations, which may even coexist not only in the same patient but also in the same joint.

3.7.1.1 Which abnormalities?

Characteristic radiographic features of PsA include joint erosions, JSN, bony proliferation including periarticular and shaft periostitis, osteolysis, ankylosis, spur formation, and spondylitis. Abnormalities are seen in the phalangeal tufts and at the sites of attachments of tendons and ligaments of the bone. Although erosive changes in early PsA are marginal as in RA, they become irregular and ill-defined with disease progression because of periosteal bone formation adjacent to the erosions. In severe cases, erosive changes may progress to development of pencil-in-cup deformity or gross osteolysis. These features are typical of arthritis mutilans.

3.7.1.2 Which joints?

Joint involvement in PsA is often asymmetrical and may be oligoarticular. Asymmetrical erosions may be visible radiographically in the carpus and in the MCP, PIP and DIP joints of the hands, but the DIP joints are often the first to be affected. The hands tend to be involved much more often than the feet with a ratio of nearly 2:1. Erosive changes and bone proliferation in the feet usually involve the IP and MTP joints: the IP joint of the great toe is most often affected. Radiographs of the hand are most important in the follow-up of patients, but addition of films of the feet makes the picture more complete.

Spondylitis is a characteristic feature of PsA and may be difficult to distinguish from AS radiographically. Syndesmophytes occur in both PsA and AS, but in PsA they may be Para marginal and do not appear in consecutive vertebrae. Sacroiliitis is relatively common and often unilateral.

3.7.2 Scoring methods: general introduction

Development and validation of scoring methods for PsA are less advanced than for RA. All the presently used methods have as their basis the scoring methods used for RA. Table 8 summarises the two global scoring methods and two detailed scoring methods, which will be described below.

Global score each joint

- ➡ Modified Steinbrocker score (hands-feet)
- ➡ Ratingen method for PsA (separately destruction-proliferation)

Detailed score each joint

- ➡ Sharp method (RA, but 2 extra scores erosion, 1 extra score JSN)
- ➡ Van der Heijde modification of Sharp method

3.7.3 Global assessment for each joint

3.7.3.1 Modified Steinbrocker score

The modified Steinbrocker score was developed at the PsA clinic at the University of Toronto (Rahman et al, 1998). Each joint is scored on a 0–4 scale, where 0 is normal; 1 reflects juxta-articular osteopenia or soft tissue swelling; 2 is the presence of erosion; 3 is the presence of erosion and JSN; 4 is total joint destruction, either lysis or ankylosis. This score is applied to 14 joints in each hand and six joints in each foot. The range of the score is from 0 to 160.

3.7.3.2 Psoriatic Arthritis Ratingen Score

The Psoriatic Arthritis Ratingen Score (PARS) includes 40 joints of the hands and feet (Wassenberg et al, 2001). All joints are scored separately for destruction and proliferation. The **destruction score** is based on the amount of joint surface destruction on a **0–5 scale**, with 0, normal; 1, one or more definite erosions with an interruption of the cortical plate of >1 mm but destruction of <10% of the total joint surface; 2, destruction of 11–25%; 3, destruction of 26–50%; 4, destruction of 51–75%; 5, destruction of >75% of the joint surface. The **proliferation score** considers any kind of bony proliferation typical for PsA on a **0–4 scale**, with 0, normal; 1, bony proliferation measured from the original bone surface of 1–2 mm or, if the margins of the proliferation cannot be distinguished from the original bone surface, clearly identifiable bone growth not exceeding 25% of the original diameter of the bone; 2, bony proliferation of 2–3 mm or bone growth between 25–50%; 3, bony proliferation >3 mm or bone growth >50%; 4, bony ankylosis. The destruction score with a range from 0 to 200 and the proliferation score with a range from 0 to 160 are summed to give the **total score** (0–360).

Table 8 Comparison of radiographic scoring methods for psoriatic arthritis

	Modified Steinbrocker (Global score)	Ratingen method for PsA (Global score)	Sharp method (Detailed score)	van der Heijde modification of Sharp method (Detailed score)
<i>Films</i>				
Hands	X	X	X	X

Total	0–160	0–360	0–470	0–528

*Combined with the JSN score.

[†]Erosions for hands 0–5, for feet 0–10.

DIP, distal interphalangeal; IP, interphalangeal; JSN, joint space narrowing; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

3.7.4 Detailed scoring methods

3.7.4.1 PsA scoring method based on Sharp scoring method for RA

The erosion scale used in RA has a range of 5 per joint (cfr supra 2.6.4.1). The erosion scale was expanded with the scores of 6 and 7 to accommodate more extensive bone destruction seen in many cases of PsA, such as gross osteolysis or a pencil-in-cup lesion. However, the scores of 6 and 7 are not added to get the total erosion score, but these features are kept separately. The **erosion score** is applied to 21 joints in each hand (0-5) and six joints in each foot (0-5), resulting in a range of 0–210 for hands and 0–60 for feet. The **scoring of JSN** is on a scale of 0–4 and is used as for RA with the addition of widening (score 5), which is automatically scored when gross osteolysis is present. Again the score for widening is not included in the total narrowing score but analysed as a separate feature. The JSN score is applied to 20 joints in each hand (0-4) and five joints in each foot (0-4), leading to a range of 160 for hands and 40 for feet.

3.7.4.2 Sharp/van der Heijde modified scoring method for PsA

A scoring system similar to that used in RA is applied to PsA (van der Heijde et al, 2005). The same joints are scored for erosions (16 in the hands and 6 in the feet) and JSN (15 in the hands and 6 in the feet), with the addition of the eight DIP joints (=both hands) for erosions and the eight DIP joints (=both hands) and two IP joints of the thumb for JSN. Again, the maximum score for erosions is 5 in the joints of the hands and 10 in the joints of the feet. **Scores for erosions** are applied as follows: 0, no erosions; 1, discrete erosion; 2, large erosion not passing the middle-line; 3, large erosion passing the middle-line; a combination of the above scores may lead to the maximum of 5 per entire joint in the hands; and 5 at each site of the joint (for the entire joint a maximum of 10) in the feet. The so-called **JSN score** is based on the following features: 0, normal; 1, asymmetric or minimal narrowing up to a maximum of 25%; 2, definite narrowing with loss of up to 50% of the normal space; 3, definite narrowing with loss of 50–99% of the normal space or subluxation; 4, absence of a joint space, presumptive evidence of ankylosis or complete luxation. Gross osteolysis and pencil-in-cup lesions are scored separately. In the final **summary score**, joints with one of these abnormalities get the maximum score assigned for both erosions and for JSN. The total range for erosions is 200 for the hands, 120 for the feet; the total range for JSN is 160 for the hands and 48 for the feet, giving a total possible score of 528.

3.7.5 Assessment of structural damage in clinical practice

No recommendation exists on the assessment of structural damage in routine clinical practice in PsA. The methods are not validated sufficiently. Based on feasibility, the modified Steinbrocker approach seems the most appropriate candidate, but little is known about its usefulness and validity for monitoring disease in clinical practice.

3.8 Magnetic resonance imaging

The clinical appearance of PsA is diverse, involving the spine, sacroiliac (SI) joints, peripheral joints and/or entheses and, accordingly, imaging findings vary. Imaging in PsA (Ory et al, 2005; McQueen et al, 2006) has received less research scrutiny than in RA and AS, but this is likely to change, as MRI outcome measures are increasingly being used in clinical trials of new therapeutic agents.

3.8.1 Which abnormalities?

PsA shares clinical manifestations with RA and spondyloarthritis (SpA) and also shares MRI features. Peripheral PsA synovitis appears to be similar to RA synovitis on MRI. Similarly, PsA bone erosions do not have disease-specific MRI features. MRI bone oedema can involve any of the wrist or finger bones. As in other spondyloarthritides, enthesitis, dactylitis and spondylitis can be seen. Enthesitis may occur adjacent to peripheral and axial joints, often associated with synovitis and sometimes with bone oedema. Dactylitis has been shown on MRI to be due to tenosynovitis with effusion, sometimes associated with synovitis in nearby finger or toe joints. Diffuse soft tissue oedema may overlie areas of dactylitis, synovitis or bone oedema. There are few MRI studies in axial PsA, but as in AS, findings in SI joints and the spine include bone oedema, erosions, periarticular fat accumulation and sclerosis.

3.8.2 Which joints?

PsA affects both axial and peripheral joints and entheses, and a general agreement on which joints to image to assess PsA activity and damage has not been established and possibly needs to be individualised, based on the disease pattern.

3.8.3 Methods for assessment

Most studies report only qualitative MRI assessments of the different pathologies of PsA. Quantitative assessment of contrast uptake has been reported in one study. No generally accepted or validated methods for assessment of PsA activity or damage exist. An OMERACT PsA MRI scoring system (**PsAMRIS**) has been developed for use in PsA hands (Østergaard et al, 2009). Discussions of appropriate MRI sequences and consensus MRI definitions of important pathologies are also provided. The scoring system has been shown to be reliable in hands and feet (McQueen et al, 2009; Glinatsi et al, 2015), however further testing and validation of the score is warranted.

3.8.4 Predicting and monitoring disease activity and damage: implications for clinical practice

It remains to be determined whether any MRI features predict subsequent joint damage in PsA.

MRI has disclosed evidence of subclinical arthritis in a high proportion of patients with psoriasis alone, suggesting that PsA may be a much more common disorder than has previously been suspected and that MRI could improve disease activity assessment in PsA.

3.9 Ultrasonography

Little research into the use of US in PsA has been carried out. However, in peripheral joints and entheses, the same advantages and disadvantages as for RA apply. US is not suited for assessment of axial disease, as changes are generally located at sites inaccessible to US examination.

3.9.1 Which abnormalities?

In areas accessible to US examination in the limbs of patients with PsA, US can be used to assess synovitis (synovial hypertrophy or Doppler signal, or both), joint effusion, bone erosions, tenosynovitis and enthesitis. For instance, enthesitis at the Achilles tendon is identified by US much more frequently than on clinical examination in patients with psoriasis and PsA. However, the sonographic findings are non-specific, as they may also occur in other diseases such as osteoarthritis and RA. US may be a useful tool for assessing dactylitis and visualising tenosynovitis, joint effusion, and synovitis.

3.9.2 Which joints?

PsA affects both axial and peripheral joints and entheses and a general agreement on which joints to image to assess activity and damage has not been established. This possibly needs to be individualised, based on the disease pattern.

3.9.3 Methods for assessment

Only qualitative US assessments of the different pathologies of PsA have been reported. No generally accepted or validated methods for assessment of PsA activity or damage exist.

3.9.4 Predicting and monitoring disease activity and damage: implications for clinical practice

It remains to be determined whether any US features predict subsequent joint damage in PsA. The value of longitudinal monitoring by US in patients with PsA for joint and enthesal manifestations, although likely, has not been scientifically documented.

4 Axial spondyloarthritis

4.1 Core set

Many instruments are available which can be used to assess axial SpA (*Machado et al, 2011). The Assessment in SpondyloArthritis international Society (ASAS) has proposed several core sets for use in clinical trials to

evaluate disease-controlling anti-rheumatic treatment, symptom-modifying anti-rheumatic drugs and physical therapy, as well for use in clinical practice (Zochling et al, 2006). All core sets comprise several domains and for each domain one or several instruments have been selected. Table 9 presents the domains and respective instruments for the various core sets, which will be discussed in more detail. The domains of *pain*, *patient global assessment of disease activity*, *morning stiffness*, *fatigue*, *spinal mobility* and *physical function* are included in all core sets. All the assessments described in this chapter were initially developed for AS but are currently applied both in radiographic (i.e., AS) and non-radiographic axial SpA. These assessments are presented in detail in the ASAS handbook (*Sieper et al, 2011), which can be accessed at the Annals of the Rheumatic Diseases website (<http://www.ard.bmj.com>) or the ASAS website (<http://www.ASAS-group.org>).

Patient global assessment: The patient is asked to place a mark on a VAS or an NRS to represent their response to the question: ‘How active was your spondylitis on average last week?’

Pain: Patients are asked two questions about the pain experienced, on average, over the previous week—‘How much spine pain did you experience due to AS?’ and ‘How much spine pain did you experience at night due to AS?’ Patients indicate their response on a VAS or NRS.

Spinal stiffness: The patient is asked, ‘On average last week, for how long after you woke up did you experience stiffness in your spine?’ This is recorded in minutes or on a VAS with a maximum score of 2 h. Often also the intensity of spinal stiffness is assessed by the question, ‘How would you describe the overall level of morning stiffness you have had from the time you wake up?’ The final result for spinal stiffness is the average of duration and intensity of morning stiffness.

Fatigue: One general question is asked about the average level of fatigue in the previous week, ‘How would you describe the overall level of fatigue/tiredness you have experienced?’ This, too, is answered on a VAS or NRS.

Physical function: Two indexes are available to assess functional capacity: the Bath Ankylosing Spondylitis Functional Index (BASFI) and the Dougados Functional Index (Calin et al, 1994; Dougados et al, 1988). The **BASFI** consists of 10 questions, answered on a VAS or NRS. The final score is the average of the scores for the 10 questions, ranging from 0 (no limitation in function) to 10 (maximal limitation) (box 10). The **Dougados Functional Index** has 20 questions, which are answered on a 3-point or 5-point verbal rating scale and summed to give a total score. The answers are scored 0, 1 and 2 or 0, 0.5, 1, 1.5 and 2, respectively, to ensure that the final score always falls in the range 0–40. Both functional indexes have been shown to be valid and sensitive in differentiating between groups of patients with a different level and/or improvement in physical function. There seems to be little difference between the two instruments in their sensitivity to change. The BASFI is the most commonly used instrument. Several language versions can be found on the website <http://www.ASAS-group.org> (accessed 7 September 2016).

Table 9 Specific instruments for each domain in core sets for DC-ART, SMARD, physical therapy and clinical record keeping

Domain	Instrument
Function*	BASFI
Pain*	NRS/VAS [§] , past week, spine, at night due to AS <i>and</i> NRS/VAS, past week, spine, due to AS
Spinal mobility*	Chest expansion <i>and</i> modified Schober <i>and</i> occiput to wall <i>and</i> cervical rotation <i>and</i> (lateral spinal flexion or BASMI)
Patient global*	NRS/VAS, global disease activity past week
Peripheral joints and entheses [†]	Number of swollen joints (44-joint count) Validated entheses score, such as MASES, San Francisco and Berlin
X-Ray spine [‡]	Lateral lumbar spine <i>and</i> lateral cervical spine
Stiffness*	NRS/VAS duration of morning stiffness, spine, past week
Acute phase reactants [†]	CRP or ESR
Fatigue*	Fatigue question BASDAI

*Included in core sets for DC-ART, SMARD/physical therapy and clinical record keeping.

§Use of an NRS is preferred by ASAS.

AS, ankylosing spondylitis; ASAS, Assessment in SpondyloArthritis international Society; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BASFI, Bath Ankylosing Spondylitis Functional Index; BASMI, Bath Ankylosing Spondylitis Metrology Index; CRP, C reactive protein; DC-ART, disease-controlling antirheumatic treatment; ESR, erythrocyte sedimentation rate; NRS, numerical rating scale; SMARD, symptom-modifying antirheumatic drug; VAS, visual analogue scale.

Box 9 Bath Ankylosing Spondylitis Functional Index (BASFI)

- Putting on your socks or tights without help or aid (e.g., sock aids)
- Bending forward from the waist to pick up a pen from the floor without an aid
- Reaching up to a high shelf without help or aids (e.g., helping hand)
- Getting up out of an armless dining room chair without using your hands or any other help
- Getting up off the floor without help from lying on your back
- Standing unsupported for 10 min without discomfort
- Climbing 12–15 steps without using a handrail or walking aid (one foot each step)
- Looking over your shoulder without turning your body
- Doing physically demanding activities (e.g., physiotherapy exercises, gardening or sports)
- Doing a full day's activities whether it be at home or at work

Spinal mobility: Assessment of the spinal mobility domain involves the use of the following five instruments:

- *Chest expansion.* The patient is asked to rest his/her hands on or behind their head. The difference between maximal inspiration and expiration is then measured anteriorly at the fourth intercostal level (e.g., 5.1 cm). The better of two such measurements should be recorded.
- *Modified Schober test.* The doctor makes a mark on the patient's skin on the imaginary line between the two superior, posterior iliac spines. A second mark is then made 10 cm higher than the first mark. The patient is asked to bend forward as far as he/she can and the distance between the two marks on the skin is measured. The increase in the distance is noted (e.g., if 14.3 cm is the distance measured between the lines when the patient is bent forward maximally, the recorded result would be 4.3 cm). The better of two tries is recorded.
- *Occiput-to-wall test.* The patient stands with the heels and back against a wall and with hips and knees as straight as possible. The chin should be held at the usual carrying level. The patient is asked to try as hard as he/she can to touch his/her head against the wall. The distance between the wall and the occiput is then measured in centimetres (e.g., 9.6 cm). The better of two tries is recorded. For the Bath Ankylosing Spondylitis Metrology Index (BASMI), the tragus-to-wall distance is used (see below). Comparison of the two measures showed that both behave similarly. Because the normal situation is clear for the occiput to wall (0) and not for the tragus to wall (dependent on the size of the head) there is a preference for use of the occiput-to-wall distance.
- *Lateral spinal flexion.* The patient stands as close to a wall as possible, with the shoulders level. The distance between the patient's middle fingertip and the floor is measured with a tape measure. The patient is asked to bend sideways as far as they can without bending the knees or lifting the heels, while keeping the shoulders against the wall. The new distance from middle fingertip to floor is measured and the difference between the two is noted. The better of two tries is recorded for full left and right lateral flexion. The mean of the left and right values gives the final result for lateral spinal flexion (expressed in centimetres to the nearest 0.1 cm)
- *Cervical rotation.* The patient sits straight on a chair; chin level, hands on the knees. The assessor places a goniometer at the top of the head in line with the nose. The assessor asks the patient to rotate the neck maximally to the left, follows with the goniometer, and records the angle between the sagittal plane and the new plane after rotation. A second reading is taken and the better of the two is recorded for the left side. The procedure is repeated for the right side. The mean of left and right is recorded in degrees (0–90°) (normal > 70°).

Peripheral involvement: The 44-swollen joint count should be assessed.

Enthesitis: A few validated enthesitis scores are available for clinical studies but none of these has yet been selected as the preferred instrument.

4.2 Composite measures

The most widely used composite measure in axial SpA is the Bath AS Disease Activity Index (**BASDAI**), an entirely patient-oriented outcome measure including an assessment of *back, pain of entheses, pain or swelling of peripheral joints, fatigue, and morning stiffness* (figure 8) (Garrett et al, 1994). This measure is often used in clinical trials but also in clinical practice, especially for defining disease activity for the start of TNF blockers. The BASDAI is closely linked to patient global assessment but not to the doctor global assessment of disease activity. Several language versions can be found on the website <http://www.asas-group.org> (accessed 7 September 2016).

A composite measure for the *assessment of spinal mobility* is also available: the **BASMI**. This is a combination of the lateral lumbar flexion, tragus-to-wall distance, modified Schober, cervical rotation and intermalleolar distance (as a measure of hip function) (figure 8). The intermalleolar distance is not a measurement endorsed by the ASAS. Figure 9 describes the measurement of the BASMI. Assessment on a 10-point scale or on a linear scale as presented in figure 9 is the best-answer modality.

Recently, a composite disease activity index combining domains considered relevant by patients and clinicians has been developed as an ASAS initiative (box 10) (Lukas et al, 2009; van der Heijde et al, 2009). The **AS Disease Activity Score (ASDAS)** comprises three items from BASDAI: (1) back pain (BASDAI question 2); (2) peripheral pain/swelling (BASDAI question 3); and (3) duration of morning stiffness (BASDAI question 6), as well as patient's global assessment and one acute phase reactant (CRP or ESR). The preferred formula is ASDAS-CRP; the alternative formula is ASDAS-ESR. For clinical use the ASDAS is grouped into inactive, moderate, high and very high disease activity (figure 10) (*Machado et al, 2010). These disease activity states apply to both formulas. However, at the individual level, ASDAS-CRP and ASDAS-ESR values should not be used interchangeably. An ASDAS online calculator is available at: http://www.asas-group.org/clinical-instruments/asdas_calculator/asdas.html.

Figure 9 Bath Ankylosing Spondylitis Metrology Index (BASMI).**BASMI**

Bath ankylosing spondylitis metrology index, a combined index to assess the spinal mobility in patients with ankylosing spondylitis

Name: _____

Date: _____

- 1 Lateral lumbar flexion: patient stands with heels and buttocks touching the wall, knees straight, shoulders back, hands by the side. The patient is then asked to bend to the right side as far as possible without lifting the left foot/heel or flexing the right knee, and maintaining a straight posture with heels, buttocks, and shoulders against the wall. The distance from the third fingertip to the floor when patient bends to the side, is subtracted from the distance when patient stands upright. The manoeuvre is repeated on the left side.

Mean of right/left

- 2 Tragus-to-wall distance: maintain same starting position as above. The distance between tragus of the ear and wall during maximal effort to draw the head back without raising the chin above its usually carrying level is measured on both sides to the nearest 0.1 cm, using a rigid ruler. Ensure no cervical extension, rotation, rotation, flexion or side flexion occurs.

Mean of right/left

- 3 Lumbar flexion (modified schober): set marks in upright position at the level of the spinous process of L5 (found as the first process below the projected line across the back at the level of the top of the iliac crest) and 10 cm above the first mark. Measure distraction of the marks when the patient bends forward as far as possible, keeping the knees straight.

- 4 Intermalleolar distance: patient supine on the floor or a wide plinth, with the knees straight and the feet pointing straight up. Patient is asked to separate legs along the resting surface as far as possible. Distance between medial malleoli is measured.

- 5 Cervical rotation: patient supine on plinth, head in neutral position, forehead horizontal (if necessary head on pillow or foam block to allow this, must be documented for future reassessments). Gravity goniometer placed centrally on the forehead. Patient rotates head as far as possible, keeping shoulders still, ensure no neck flexion or side flexion occurs, Rotational angle to the right and to the left is measured.

If you do not have a gravity goniometer: patient sits with shoulders to the wall. Place goniometer to the wall above the patient's head. Patient rotates head as described above. Examiner aligns goniometer branch parallel to sagittal plane of the head.

Mean of right/left

BASMI:
(average
of 5 scores)

Box 10 ASDAS formulas**ASDAS-CRP**

$(0.12 \times \text{back pain}) + (0.06 \times \text{duration of morning stiffness}) + (0.11 \times \text{patient's global assessment}) + (0.07 \times \text{peripheral pain/swelling}) + [0.58 \times \ln(\text{CRP}+1)]$

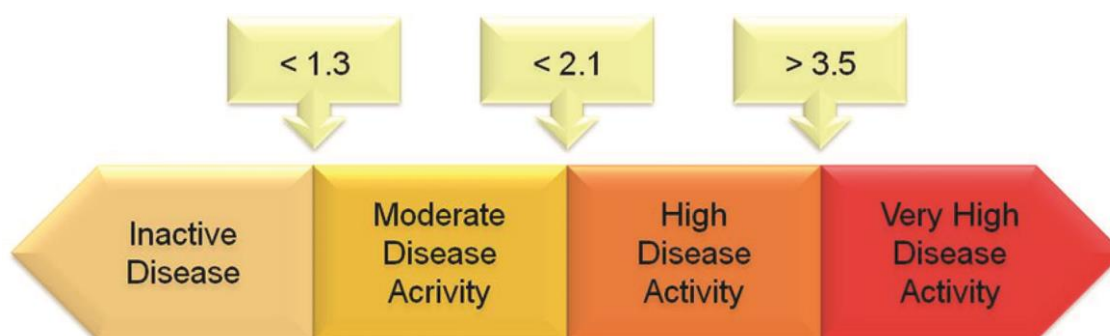

ASDAS-ESR

$(0.08 \times \text{back pain}) + (0.07 \times \text{duration of morning stiffness}) + (0.11 \times \text{patient's global assessment}) + (0.09 \times \text{peripheral pain/swelling}) + [0.29 \times \sqrt{\text{ESR}}]$

ASDAS, Ankylosing Spondylitis Disease Activity Score; CRP, C reactive protein (mg/L); ESR, erythrocyte sedimentation rate (mm/h); Ln, natural logarithm.

All questions are scored using a 0–10 VAS/NRS. In ASDAS-CRP, when the conventional CRP is below the limit of detection or when the high sensitivity CRP is <2 mg/L, the constant CRP value of 2 mg/L should be used to calculate ASDAS-CRP.

Figure 10 The Ankylosing Spondylitis Disease Activity Score (ASDAS) cut-offs for disease activity states
(Source: Assessment of SpondyloArthritis international Society (ASAS) www.asas-group.org).

The ASDAS is a reliable measure of disease activity in both radiographic and non-radiographic axial SpA and is responsive to change during treatment (Pedersen et al, 2010). Evidence accumulated during recent years supports the replacement of the BASDAI and previously used response criteria (section 4.3) by the ASDAS tool and its disease activity status and improvement cut-offs (section 4.3). The ASDAS has been received extremely well by professionals working in the field of axial SpA and is already starting to replace the BASDAI. Indeed, the ASDAS is currently being used as an outcome measure in several clinical trials and observational studies. The availability of online, desktop and handheld ASDAS calculators, as well as a quick ASDAS calculator paper form (available at www.asas-group.org), will facilitate its implementation in clinical practice.

4.3 Response criteria

The **ASAS 20 response criteria** have been widely used in clinical trials in AS (Anderson et al, 2001). The ASAS 20 criteria are based on four variables: function (BASFI), morning stiffness (inflammation—mean of morning stiffness questions of BASDAI), patient global assessment of disease activity, and overall pain (figure 11). To fulfil the ASAS 20 response criteria, there should be a 20% improvement with a minimum of 1 unit (on a 10-point scale) in at least three of the four domains without worsening of 20% and 1 unit in the possible

remaining domain. Two more strict criteria have been developed: the ASAS 40 and ASAS 5/6 criteria. The **ASAS 40 criteria** are based on the same four domains with a requirement of an improvement of at least 40% and 2 units in three out of the four domains without any worsening in the possible fourth domain (figure 12) (Brandt et al, 2004). For the **ASAS 5/6 criteria** again the same four domains are assessed but now expanded with an acute phase reactant and a measure of spinal mobility. To fulfil the ASAS 5/6 criteria there should be at least a 20% improvement in at least five domains (figure 13).

Figure 11 The Assessment in SpondyloArthritis international Society (ASAS) 20 improvement criteria (www.asas-group.org).

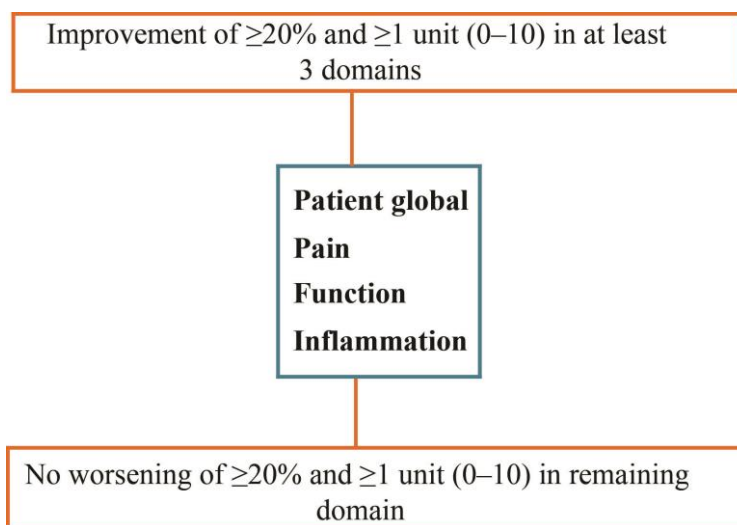

Figure 12 The Assessment in SpondyloArthritis international Society (ASAS) 40 improvement criteria (www.asas-group.org).

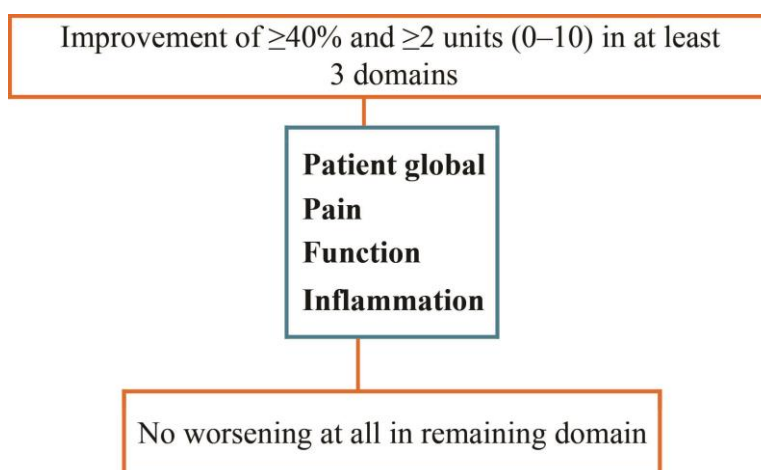

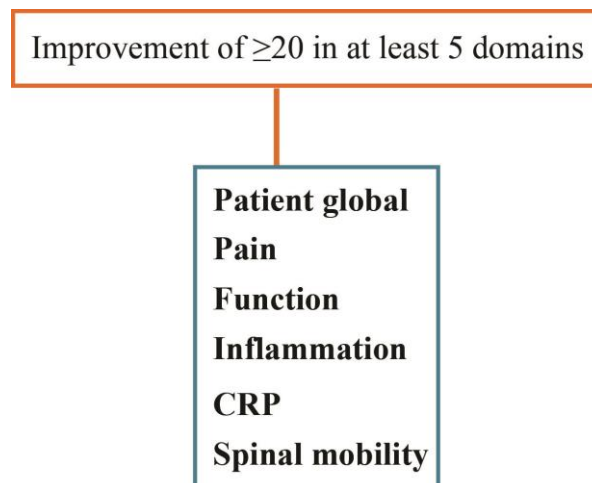

Figure 13 The Assessment in SpondyloArthritis international Society (ASAS) 5/6 improvement criteria. CRP, C reactive protein (www.asas-group.org).

Recently, **response criteria for the ASDAS** have been published. Clinically important improvement should be more than or equal to a 1.1 point improvement in ASDAS and a major improvement should be equal to or exceed 2.0 points (figure 13).

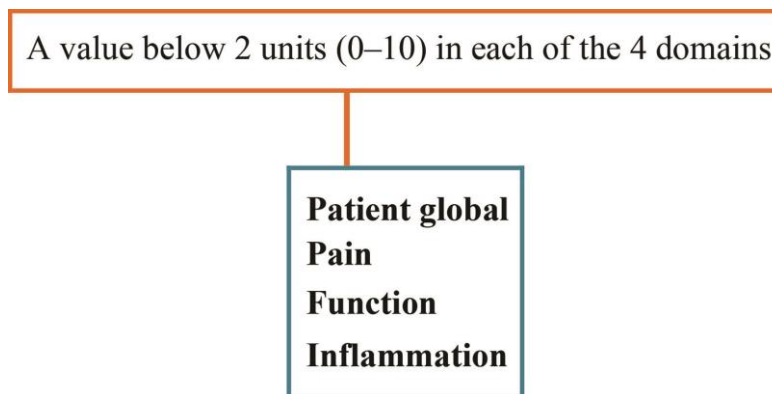

Figure 14 Selected cut-offs for improvement in the Ankylosing Spondylitis Disease Activity Score (ASDAS) (Source: Assessment of SpondyloArthritis international Society (ASAS) www.asas-group.org).

4.4 Remission, low disease activity

In addition to response criteria, **ASAS partial remission criteria** have been defined (figure 14). These are fulfilled if the value for all four domains included in the ASAS 20 response criteria is below 2. The **ASDAS cut off of <1.3** selected by ASAS to denote **inactive disease** also represents a remission-like state but the term ‘inactive disease’ was preferred by ASAS members, as remission is part of a broader concept that has not been completely defined in axial SpA and may include other features such as the absence of bone marrow oedema/osteitis (as determined by MRI). Compared with ASAS partial remission criteria, ASDAS inactive disease has the advantage of being independent of BASFI: patients with quiescent disease and a lot of structural damage who (as a consequence) have a high BASFI may never achieve ASAS partial remission, whereas they may more easily achieve ASDAS inactive disease.

Figure 15 The Assessment in SpondyloArthritis international Society (ASAS) partial remission criteria (www.asas-group.org).

4.5 The ASAS Health Index (ASAS HI)

The ASAS HI is a recently developed health index for patients with SpA based on the International classification of functioning, disability and health (ICF) core set for AS. It is important to emphasise that the ASAS HI is not a health-related quality of life instrument. It measures the burden or the impact of the disease, which encompasses different aspects of the disease (disease activity, structural damage, reduced mobility, reduced physical function, and reduced social participation) in an even more extensive way than health-related quality of life. The ASAS HI is a linear composite measure assessing ‘health’ in its broader sense and containing 17 items: (1) ‘Pain sometimes disrupts my normal activities’; (2) ‘I find it hard to stand for long’; (3) ‘I have problems running’; (4) ‘I have problems using toilet facilities’; (5) ‘I am often exhausted’; (6) ‘I am less motivated to do anything that requires physical effort’; (7) ‘I have lost interest in sex’; (8) ‘I have difficulty operating the pedals in my car’; (9) ‘I am finding it hard to make contact with people’; (10) ‘I am not able to walk outdoors on flat ground’; (11) ‘I find it hard to concentrate’; (12) ‘I am restricted in travelling because of my mobility’; (13) ‘I often get frustrated’; (14) ‘I find it difficult to wash my hair’; (15) ‘I have experienced financial changes because of my rheumatic disease’; (16) ‘I sleep badly at night’; (17) ‘I cannot overcome my difficulties’. The response option is dichotomous (‘I agree’ = score 1, or ‘I do not agree’ = score 0). All item scores are summed to give a total score that ranges from 0 (good functioning) to 17 (poor functioning). In addition, a questionnaire with a set of nine environmental factors (EF) has been proposed to address the issues of support/relationships, attitudes and health services. These EF items can act as a barrier or a facilitator and may influence the health of patients with axial SpA.

4.6 Frequency of monitoring

The frequency of monitoring in patients with axial SpA is variable and largely dependent on disease activity. With the availability of new treatments, monitoring of axial SpA is becoming more important.

4.7 Imaging assessment

4.7.1 Conventional radiographs

Radiography is the first imaging step in making the diagnosis of AS. The *anteroposterior (AP) view of the pelvis* gives sufficient information about the SI joints, making special projections unnecessary. *Lateral radiographs of the cervical and lumbar spine* give information on the severity and extent of the disease. The lateral radiograph of the thoracic spine is often difficult to interpret owing to over-projections of the ribs and other structures. AP films of the cervical spine are of little help in axial SpA; AP films of the lumbar spine do give extra information on the extent of syndesmophyte formation, although this information is rather limited and it is questionable whether it is worth the extra radiation and costs.

4.7.1.1 Which abnormalities?

The radiographic process in AS is dominated by osteoproliferation, although osteodestruction also occurs to a limited extent. Sclerosis, erosions, pseudodilatation and ankylosis are the major features. The value of the findings depends on the age of the patient because erosions and ankylosis are increasingly found in older people—this being regarded as a consequence of osteoarthritis. AS-related spinal changes can be differentiated into active (spondylitis, spondylodiscitis), structural osteodestructive (erosions), and structural hyperproliferative (enthesophytes, vertebral squaring, disc calcifications, syndesmophytes, bony bridging, vertebral ankylosis) changes. Syndesmophytes are characterised by a typical axial growth, which may lead to bridging between vertebrae in the outer, but sometimes also in the central, part of the annulus fibrosus. Furthermore, syndesmophytes may appear in the prediscal region between the intervertebral disc and the anterior intervertebral ligament.

4.7.1.2 Which sites?

Assessment of the *SI joints* is especially important for making a diagnosis (figure 16). Radiographs of the *spine* are most informative for assessing the extent of the disease and for following progression over time. *Hip* involvement is an important prognostic factor. However, radiographs of the hips should not be taken routinely, but only if clinically indicated. Moreover, if the SI joints need to be visualised, this can be done by the AP view of the pelvis, which has the major advantage of providing information about the hips as well. Assessment of peripheral joints should only be done if clinically indicated.

Figure 16 Both sacroiliac joints show some erosions, sclerosis, bony bridges, irregular joint space and ill-defined margins (bilateral grade 3 according to modified New York criteria: grade 0, normal; grade 1, suspicious for sacroiliitis; grade 2, small localised areas with erosions or sclerosis without alteration in joint width; grade 3, moderate/advanced sacroiliitis with one or more erosions, evidence of sclerosis, joint space narrowing or widening or partial ankylosis; grade 4: total ankylosis).

4.7.2 Scoring methods: general introduction

Three methods have specifically been designed for the assessment of structural damage in AS. Table 10 summarises the various characteristics of the scoring methods. All methods are suitable for assessing damage in the spine. In addition, scoring methods for the SI joints exist, as well as one specific method for assessment of the hips in AS.

Global spine

➔ BASRI (AP and lateral, SI joints, lumbar and cervical spine), BASRI hip, BASRI total

Detailed spine

➔ modified SASSS (lateral cervical and lumbar spine, anterior corner)

4.7.3 Global assessment of the spine

4.7.3.1 Bath Ankylosing Spondylitis Radiological Index

The Bath Ankylosing Spondylitis Radiological Index (BASRI) spine has three components: the SI joints, the lumbar, and the cervical spine (Calin et al, 1999). A global score ranging from 0 to 4 (normal, suspicious, mild, moderate, and severe) is applied to each component. The SI joints are scored according to the four grades of

the modified New York criteria (0-4). To assess the lumbar spine, lateral and AP views are used. The score for the lumbar spine, from the lower border of T12 to the upper border of S1, is a composite score of both views, taking all the affected levels into account in the score. The cervical spine was defined as extending from the lower border of C1 to the upper border of C7. Squaring, sclerosis, erosions, syndesmophytes and fusion are the features that are included. Syndesmophytes and fusion are the most important parts driving the scoring method. The BASRI spine is the sum of the mean score of the right and left SI joint (to one decimal place) plus the score of the lumbar spine plus the score of the cervical spine. The range for the BASRI spine is 2–12 (as patients with AS have sacroiliitis by definition, the minimum is 2). A similar grading system has been developed for the hips: the BASRI hip. The sum of the BASRI spine and BASRI hip is called the BASRI total, with a range from 2 up to 16.

Table 10 Comparison of radiographic scoring methods for ankylosing spondylitis

	BASRI	SASSS	Modified SASSS
<i>Films</i>

Per joint/vertebra global	0–4	–	–
Total	2–12/16 [†]	0–72	0–72

**Without the hips, three sites (cervical, lumbar spine and SI joints) are scored, including the hips, four sites.*

†Without the hips the range is up to 12, including the hips the range is up to 16.

‡Four corners of six vertebrae are scored.

§The two anterior corners of 12 vertebrae are scored.

AP, anteroposterior; BASRI, Bath Ankylosing Spondylitis Radiological Index; SASSS, Stoke Ankylosing Spondylitis Spine Score; SI, sacroiliac.

4.7.4 Detailed assessment of the spine

4.7.4.1 Stoke Ankylosing Spondylitis Spine Score

The Stoke Ankylosing Spondylitis Spine Score (SASSS) is a detailed scoring system for the anterior and posterior site of the lumbar spine and includes the lower border of the 12th thoracic vertebra, all five lumbar vertebrae, and the upper border of the sacrum on a lateral view (Taylor et al, 1991). All four corners of each vertebra are examined and scored 1 for an erosion, sclerosis and/or squaring, 2 for a syndesmophyte, and 3 for total bony bridging, giving a maximum possible score of 72 (total of 24 corners).

4.7.4.2 Modified Stoke Ankylosing Spondylitis Spine Score

The modified Stoke Ankylosing Spondylitis Spine Score (mSASSS) is a modification of the SASSS and scores the anterior site of the lumbar and cervical spine at a lateral view (Creemers et al, 2005). The anterior corners of the cervical spine from the lower border of C2 to the upper border of T1, and the anterior corners of the lumbar spine from the lower border of T12 to the upper border of S1, are scored (total of 24 corners). The scoring of features is identical to the SASSS. The range is also 0–72. The **mSASSS** has been selected as the *preferred method for assessing structural damage in the spine* by ASAS and OMERACT, based on favourable reproducibility and sensitivity to change (Wanders et al, 2004).

4.7.5 Assessment of structural damage in clinical practice

Given the slow progression rate of structural damage in axial SpA, it is recommended that regular radiographs should be taken at an interval of ≥ 2 years. Either BASRI or mSASSS could be used as scoring methods. The disadvantage of the BASRI is the ceiling effect: patients may reach the maximum score while still showing progression. Another disadvantage is that an AP film of the lumbar spine is needed with extra radiation exposure, but this yields only limited extra information.

4.8 Magnetic resonance imaging

The axial skeleton is the main target for axial SpA and, owing to its ability to visualise inflammatory changes in bone and soft tissues, MRI is the most sensitive modality for imaging early spine and SI joint changes. Axial SpA

may also involve peripheral arthritis and enthesitis, which can also be visualised by MRI (Hermann et al, 2004; Maksymowych et al, 2006).

4.8.1 Which abnormalities?

Inflammatory lesions of the spine, which can be visualised by MRI, are: anterior/posterior spondylitis (figure 17A), spondylodiscitis and arthritis of the zygapophyseal (figure 17B), and costovertebral joints. Spinal structural lesions include: fatty deposition (figure 17C), erosions, syndesmophytes, and ankylosis. Findings indicating active disease in the SI joints (sacroiliitis) include juxta-articular bone marrow oedema (figure 18A), capsulitis, and enhancement of the joint space after contrast medium administration, while visible chronic changes include bone erosions, sclerosis, fatty deposition (figure 18B), and trans articular bone bridges/ankylosis. Enthesitis is also common and may affect the interspinous and supraspinous ligaments of the vertebral spine and the interosseous ligaments in the retroarticular space of the SI joints. Some patients also have disease manifestations in peripheral joints and entheses and these can be visualised by MRI as in other diseases.

Figure 17 (A) Anterior spondylitis: STIR image showing corner bone marrow oedema at T4/5, T6/7 and T8/9. (B) Arthritis of the zygapophyseal joints: STIR image showing inflamed facet joints at L1/2. (C) Fatty deposition: T1 image showing high signal intensity due to fatty deposition at L5/S1 anterior vertebral corners. STIR, short tau inversion recovery.

4.8.2 Which joints and how to acquire images?

Most MRI studies of the SI joints have used only one imaging plane (semicoronal, i.e., parallel with the axis of the sacral bone). To be maximally sensitive for changes in the ligamentous portion of the SI joints, imaging in

two perpendicular planes is required. This is particularly important when MRI is used for diagnosis, though probably less important when used as an outcome measure in trials.

Similarly, the majority of MRI studies of the axial SpA spine involve only sagittal images, which are not optimal for visualising changes in the apophyseal and costovertebral joints. The importance of such changes remains to be determined.

There is general agreement that adequate MRI of the axial SpA spine, as of the SI joint, must at least include a *T1-weighted sequence without fat saturation* and a *STIR sequence in one plane*. To what extent further sequences -including post-contrast sequences and/or more planes- are needed, is debated and depends on the goal of the examination.

Figure 18 (A) Active left sacroiliitis (bone marrow oedema) in a patient with non-radiographic axial spondyloarthritis; affected bone marrow areas (oval line) are located periarticularly (STIR). (B) Fatty deposition in the same patient; T1 image showing high signal intensity due to fatty deposition (oval lines) at both sacroiliac joints. STIR, short tau inversion recovery.

4.8.3 Methods for assessment

Several scoring systems for assessment of disease activity in the SI joints and in the spine have been proposed. These have been tested against each other by the OMERACT-ASAS MRI in AS group and will be described below, followed by a description of the few systems available for assessment of chronic damage.

4.8.3.1 Activity: spine

Three different scoring systems have been developed and validated: the Ankylosing Spondylitis spine Magnetic Resonance Imaging-activity (**ASspiMRI-a**) score, grading activity 0–6 per vertebral unit in 23 units; the **Berlin modification of the ASspiMRI-a score**, grading activity 0–3 per vertebral unit in 23 units; and the Spondyloarthritis Research Consortium of Canada (**SPARCC**) scoring system, scoring only the six vertebral units considered by the reader as the most abnormal, with additional points for ‘depth’ and high ‘intensity’ of the lesion (table 11). In an OMERACT–ASAS multireader exercise, the feasibility, reliability, sensitivity to change, and discriminatory capacity of all three scoring systems in patients with AS were demonstrated. The SPARCC method had the highest sensitivity to change, as judged by Guyatt’s effect size and the highest reliability as judged by the inter-reader intraclass correlation coefficient, but not if judged by the smallest detectable change (Lukas et al, 2007).

Table 11 MRI scoring methods for assessment of the spine in ankylosing spondylitis

	Activity			Damage
	SPARCC	ASspiMRI-a	Berlin	ASspiMRI-c
Images	Sagittal STIR	Sagittal post-Gd T1-weighted FS + sagittal STIR	Sagittal post-Gd T1-weighted FS + sagittal STIR	Sagittal T1-weighted
Area	Six most affected DVUs	All 23 DVUs	All 23 DVUs	All 23 DVUs
Features	Bone marrow oedema	Bone marrow oedema/enhancement and bone erosion	Bone marrow oedema/enhancement	Sclerosis, squaring, syndesmophytes and bridging/fusion
Grades	0–1 per DVU quadrant + 1 for depth ≥ 1 cm and 1 for high intensity of lesion	0–6 per DVU	0–3 per DVU	0–6 per DVU
Total score range	0–108	0–138	0–69	0–138

ASspiMRI-a, Ankylosing Spondylitis spine Magnetic Resonance Imaging-activity; *ASspiMRI-c*, Ankylosing Spondylitis spine Magnetic Resonance Imaging-chronicity (Braun et al, 2003); *Berlin method* (Braun et al, 2004); *SPARCC*, Spondyloarthritis Research Consortium of Canada (Maksymowych et al, 2005).

DVU, disco vertebral unit defined as the region between two virtual lines through the middle of each vertebra and includes the intervertebral disc and the adjacent vertebral end plates (Figure 19); FS, fat saturated; Gd, intravenous injection of gadolinium-containing contrast agent; SpA, spondyloarthritis; STIR, short tau inversion recovery.

Figure 19: Definition of a DVU (Braun et al, 2004)

4.8.3.2 Activity: sacroiliac joints

Three main scoring approaches have been proposed, based on either global scores per quadrant or individual scores in consecutive semicoronal images through the joint (table 12).

Table 12 MRI scoring methods for assessment of the sacroiliac joints in ankylosing spondylitis

	Activity			Damage	
	SPARCC	Puhakka activity	Hermann activity	Puhakka damage	Hermann damage
Images	Semicoronal STIR	Pre- and post-Gd semicoronal and semi axial T1-weighted FS; semicoronal STIR	Semicoronal pre- and post-Gd T1-weighted FS and STIR	Pre-Gd semicoronal and semi axial T1-weighted and T1-weighted FS	Semicoronal pre- and post-Gd T1-weighted and T1-weighted FS
Area	SI joints, six consecutive semicoronal slices	SI joints, in two planes	SI joints, in semicoronal plane	SI joints, in two planes	SI joints, in semicoronal plane
Features	Bone marrow oedema	Bone marrow oedema, bone marrow enhancement, joint space enhancement	Bone marrow oedema, bone marrow enhancement	Erosion, sclerosis, joint space width	Erosion, sclerosis, joint space width, bone bridging/ankylosis
Grades	In each slice: 0–1 per quadrant + 1 for depth ≥ 1	Marrow oedema: 0–3 per quadrant; marrow enhancement: 0–3 per quadrant; joint	Global: 0–3 per quadrant	Erosion: 0–3 per quadrant; sclerosis: 0–3 per quadrant;	Global: 0–4 per joint

	cm and 1 for high intensity	space enhancement: 0–3 per joint		joint space: 0–3 per joint	
Total score range	0–108	0–60	0–24	0–60	0–8

Hermann method: Hermann et al, 2004; Puhakka method: Puhakka et al, 2003; SPARCC, Spondyloarthritis Research Consortium of Canada: Maksymowych et al, 2005.

FS, fat saturated; Gd, intravenous injection of gadolinium-containing contrast agent; SI, sacroiliac; STIR, short tau inversion recovery.

The presence and extent of bone marrow oedema in the cartilaginous portion of the joint is the primary MRI feature that is scored, although one method also scores inflammation in the joint space and the ligamentous portion of the joint.

In an OMERACT–ASAS multireader exercise, agreement between readers and sensitivity to change were compared and found somewhat better for the most detailed scoring method (the SPARCC method).

4.8.3.3 Damage: spine and sacroiliac joints

The only method proposed for scoring the AS **spine** is the Ankylosing Spondylitis spine Magnetic Resonance Imaging-chronicity (**ASspiMRI-c**) **score**, grading chronic changes (sclerosis, squaring, syndesmophytes and fusion) 0–6 per vertebral unit in 23 units (table 11).

A scoring method for chronic changes in the **SI joints (Puhakka)** scores bone erosions and sclerosis at four osseous positions per joint (the iliac and sacral sides of the cartilaginous and ligamentous portions of the joints, respectively), as well as the joint space width (table 12). Another approach (**Hermann**) scores each sacroiliac joint 0–4 based on a global assessment of erosion, sclerosis, joint space width and bone bridging/ankylosis (table 12). Validation of the methods for damage assessment is limited and their value has not yet been clarified.

4.8.4 Predicting and monitoring disease activity and damage: implications for clinical practice

MRI allows detection and monitoring of disease activity in the spine and SI joints with a higher sensitivity than any other imaging modality and has been a major improvement in both clinical trials and practice.

Data concerning the advantage of MRI for detection of damage in SI joints and the spine compared with radiography are ambiguous and further studies are needed to clarify the role of MRI for follow-up of axial SpA damage. The prognostic significance of MRI findings, if any, has not been clarified.

4.9 Ultrasonography

US is not suitable for the assessment of axial disease, as changes are generally located at sites inaccessible to US examination. In patients with peripheral involvement US can visualise such changes as in other diseases. US has proven to be a valuable assessment of enthesal disease in axial SpA patients (D'Agostino et al, 2003). Standardised scoring systems are available, but further validity testing is required (D'Agostino et al, 2009; de Miguel et al, 2009; Naredo et al, 2010).

SUMMARY POINTS

- For a complete description of the burden of disease of a patient with an inflammatory rheumatic disease, information on disease activity, function and structural damage is needed.
- For rheumatoid arthritis (RA), psoriatic arthritis (PsA) and axial spondyloarthritis (SpA) core sets are available including the minimum assessments that should be performed in the evaluation of a clinical trial or clinical practice, or both.
- Composite measures for disease activity in RA such as the Disease Activity Score (DAS), 28-joint DAS (DAS28), Clinical Disease Activity Index (CDAI), and Simplified Disease Activity Index (SDAI) give a good indication of the level of overall disease activity and are useful in the evaluation of clinical trials and as a benchmark for tailor-made treatment.
- Response criteria in all inflammatory diseases (such as American College of Rheumatology (ACR) 20, EULAR, Assessment in SpondyloArthritis international Society (ASAS) 20, and Ankylosing Spondylitis Disease Activity Score (ASDAS) response criteria) provide limited information at the individual patient level, especially in view of longterm follow-up, and should be complemented by status scores (such as remission criteria).
- Films of hands and feet give sufficient information to determine the extent of damage on conventional radiographs in RA and follow the course of the development of damage. Several validated scoring systems exist for use in clinical trials ((modified) Sharp, Larsen method) and for use in clinical practice (Simple Erosion Narrowing Score (SENS)).
- In RA, magnetic resonance imaging (MRI) and ultrasonography (US) are highly sensitive techniques for detecting early inflammatory and destructive changes in RA joints. MRI is also sensitive to change in synovitis and erosions and is predictive of future radiographic progression.
- In axial SpA, MRI allows detection and monitoring of disease activity in the spine and sacroiliac joints with a higher sensitivity than any other imaging modality and has been a major improvement in both clinical trials and daily practice.
- The modified Stoke Ankylosing Spondylitis Spine Score (mSASSS) is the preferred method for assessing damage to the spine in axial SpA on conventional radiographs because of good reliability and sensitivity to change.
- In PsA, MRI and US can visualise activity and damage in axial (only MRI) and peripheral joints, but the value for monitoring and prognosticating PsA is not yet established.

Measuring disease activity and damage in inflammatory arthritis

Patrick Verschueren, Nathalie Berghen and Pedro Machado

A previous version was coauthored by Pernille Bøyesen, Pedro Machado, Désirée van der Heijde and Mikkel Østergaard

IN-DEPTH DISCUSSION I

Presentation and interpretation of radiographic data

Structural damage caused by inflammatory joint diseases evolves slowly over a long period of time, but with marked inter-individual variation. Scoring systems quantify the amount of damage. Sets of X-rays (e.g. hands and feet for RA) obtained with regular time intervals are scored and the sum score per patient reflects total damage at a time point. The within-patient difference occurring between two or more observations in time is considered to be the individual change (progression) score.

How to present radiographic data to the medical readership ?

A number of difficulties limit the interpretability of radiographic scores in clinical studies. The first problem is how to present radiographic data to the medical readership. Both in RA and in AS, radiographic progression scores are not normally distributed. Only a small fraction of all patients show substantial progression of damage and the majority shows no progression at all. One of the assumptions underlying the use of means and standard deviations - descriptive parametric statistics that most clinicians are familiar with - is a normal distribution of the data. Since they are not normally distributed, progression scores should not be presented (only) as mean scores with standard deviations (SD). **Means and standard deviations** calculated in a set of radiographic scores are extremely sensitive to subtle changes at the upper extreme. A better way of presenting radiographic data is by medians (the value cutting off the 50 percentile), and 25- and 75 percentiles, or by **Box & Whisker plots**, that in addition present the 5- and 95-percentile, as well as the extreme values (figure 1). Some investigators present logarithmically transformed data, which may result in a dataset with a normal distribution, but these data are even more difficult to interpret. The most important disadvantage of percentiles like the median in comparison with means and SDs is that percentiles only relate to one observation in the distribution (e.g. the median observation), and neglect the majority of the variable's values. Means and SDs are so-called inferential statistics that include all variable's values, and describe the internal coherence of the data. Since the presentation of percentiles does not admit a proper judgement of the coherence of the data, this may easily conceal irregularities in the frequency distribution of radiographic scores. This may become important if cut-off levels for clinically important progression scores are chosen: a small change in the selected cut-off level may have a major effect on the results. Ordinary presentation of data (with percentiles only) that are not normally distributed thus gives rise to a significant loss of information as compared to the presentation of data derived from a normal distribution by means and SDs. Therefore there is a consensus that the minimum presentation of radiographic data should include both the mean and SDs and the median and IQR.

Figure 1. Change in radiographic damage - example box plot

How to present differences in scores between different observations and/or observers ?

Another issue is measurement error, the phenomenon that different observers score the same X-rays differently, or one observer who scores the same X-rays twice arrives at different scores. When comparing treatment groups, measurement error is equally divided across these groups as a consequence of randomisation and blinding of readings. In uncontrolled observational studies, or in analyses within one treatment group of a comparative trial, however, measurement error can become crucial. In order to gauge part of measurement error, there is some consensus that readings in clinical trials in RA should be performed by at least two readers, and that the average score obtained by all readers should be used in analyses. Inter-observer measurement error can be made visible by **Bland & Altman plots** (see extra information below), but this technique is difficult to understand to the uninvolved audience, and therefore often not published in medical journals.

Relatively new is the use of the **cumulative probability plot** as a means of presentation of radiographic progression scores. Probability plots can be used to help the reader of the article make a proper judgement about progression, but also about differences between different observations and/or observers.

How to construct and interpret cumulative probability plots ?

Radiographic data from the COBRA trial are used to illustrate how to construct and interpret cumulative probability plots. The COBRA trial is a one-year randomised clinical trial of 135 patients that compared the effects of a strategy with combination therapy (prednisolone, methotrexate and sulfasalazine) with monotherapy (sulfasalazine only).

Table 1 summarises all observed radiographic progression scores, which are defined as the difference between the total damage score at the end of the trial and that at the start of the trial. Data were summarised by change score in 3 different ways: 1) number of patients with a particular progression score; 2) cumulative number of patients with a progression score \leq that particular score (=cumulative frequency); and 3) cumulative percentage of patients with a progression score \leq that particular score (=cumulative probability). Cumulative probability is the cumulative frequency expressed as a percentage of the total number of patients. Note that every patient contributes for an equal part ($1/135 = 0.0074$ or 0.74%) to the cumulative probability.

Table 1. Frequency distribution of radiographic progression scores of 135 patients who had participated in the COBRA trial

Progression score:	Number of patients with this score:	Patients with this score or below:	
		Cumulative frequency	Cumulative probability (%)
0	22	22	16.3
1	14	36	26.7
2	7	43	31.9
3	14	57	42.2
4	12	69	51.1
5	6	75	55.6
6	6	81	60.0
7	4	85	63.0
8	2	87	64.4
9	1	88	65.2
10	3	91	67.4
11	1	92	68.1
12	2	94	69.6
13	3	97	71.9
14	3	100	74.1
15	4	104	77.0
16	3	107	79.3
17	6	113	83.7
18	1	114	84.4
19	1	115	85.2
20	1	116	85.9
21	1	117	86.7
22	5	122	90.4
23	1	123	91.1
24	0	123	91.1

25	0	123	91.1
26	1	124	91.9
27	1	125	92.6
28	1	126	93.3
29	0	126	93.3
30	2	128	94.8
>30	7	135	100

If data such as in Table 1 (column 1 and 2) are plotted in a graph, a bar chart such as in Figure 2a can be created. **Bar charts** are useful to get an impression about the type of distribution of the data, e.g. to find out whether the data are normally distributed (bell-shaped curve). The pattern in Figure 1a is a typical example of a set of radiographic progression scores: since the change scores with the highest frequencies lie left as compared to the scores of the normal distribution, such a distribution is called skewed-to-the-left.

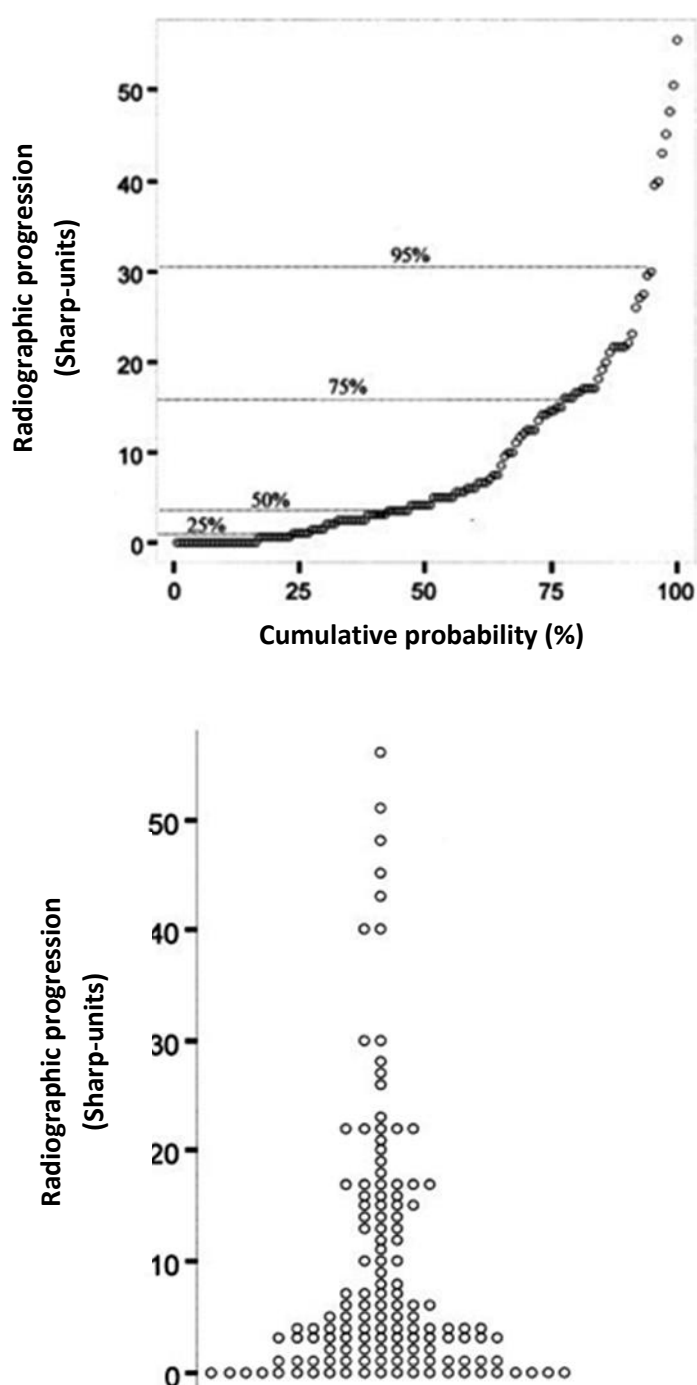

Figure 2a. Individual progression scores of 135 patients who participated in the COBRA trial. Data are visualised by histogram (Fig 2a), cumulative probability plot (Fig 2b), and dot plot (Fig 2c). See text for further explanation.

If all separate cumulative probability values (x-axis) are plotted against all separate scores (n=135) (y-axis), then a **probability plot** is created (Figure 2b). Every single change score (one score per patient) is now plotted in the graph, and represents a similar proportion of the cumulative probability (0.74%), so that the density of dots is similar along the entire range of the x-axis. The lowest scores are zero, and it is obvious from the figure that the lower range of progression scores (<10 Sharp-units) occur far more frequently than the higher range. It is easy to see which proportion of patients has a change score of zero. High and very high scores occur

sporadically, and hardly contribute to the cumulative frequency, but they importantly determine the curvature of the graph, as well as the mean and the standard deviation. The median and the 25/75 percentiles can easily be derived from the probability plot by drawing a straight line from the corresponding percentile on the x-axis through the curve (Fig 2b). The matching progression scores can be read from the y-axis. Figure 2c shows a dot plot of the same radiographic data. Dot plots also include all separate scores. Probability plots as well as dot plots allow an interpretation of the coherence of the data (irregularities, “jumps”), but it is impossible to directly interpret percentiles from a dot plot.

Figure 2b

How can cumulative probability plots be used to visualise inter-reader variability ?

Because of measurement error, readings of X-rays are usually performed by two or more readers. Cumulative probability plots can be used to visualise inter-reader variability, and to explore trends. Figure 3a shows the probability plot of change scores obtained by two independent readers who scored the same sets of X-rays of AS-patients from the OASIS cohort (2 years progression scores) according to the modified SASSS. At first glance, it is obvious that reader 1 scores somewhat higher than reader 2. Reader 1 sees some progression in a greater proportion than reader 2 (is more sensitive to change), but sees negative scores in a smaller proportion than reader 2 (sensitivity to change is not at the cost of specificity here). As compared to reader 2, the entire curve of reader 1 is translated to the left.

Extra information: Bland & Altman plot, another instrument to visualize inter- and intra-reader variability

Bland & Altman plots can be used to assess agreement between readers. These plots present the difference in progression scores between two readers on the y-axis against the average progression score of the readers on the x-axis. Figure 3b displays the same data as Figure 3a but now in the format of a Bland & Altman plot. Again, it is obvious that reader 1 scores a little bit higher (represented by a mean negative difference between the readers (dotted line), but additional information is difficult to deduct from this plot. What are the differences between probability plots and Bland & Altman plots? First, the actual progression scores can be easily and directly depicted from the probability plot. It requires additional inference if you want to get this information from a Bland & Altman plot. As an example, the dot designated with an arrow in Fig 3b (the mean score of 5 and the difference score of -4 comprises an actual score of $+3$ by reader 1, and of $+7$ by reader 2). Second, in probability plots, unlike Bland & Altman plots, the scores of two readers for a particular value of the x-axis do not necessarily belong to the same patient. Third, probability plots can simultaneously plot the scores of more than two readers, which is not possible with Bland & Altman plots. An advantage of probability plots is that these are appropriate for investigating the coherence of the data of the group, with presentation of the actual progression scores. It should be noted however, that probability plots are not appropriate to quantify measurement error, which can be done by using the data of the Bland & Altman plot. Therefore, both types of plots give complementary information, and it depends on the data and the study question to use either of them or both.

Figure 3. Cumulative probability plots (Fig 3a) and Bland & Altman plot (Fig 3b) of individual 2-years radiographic progression scores (in modified SASSS-units) in 109 patients with ankylosing spondylitis who had participated in the OASIS cohort. Every patient was scored twice by two different readers (open circles and open triangles), who both read with concealed time order.

Figure 3a

Figure 3b

Note: a circle and a triangle with similar cumulative probability (Fig 3a) do not necessarily belong to the same patient. Every dot in the Bland & Altman plot (Fig 3b) refers to the same patient scored by two readers, but one symbol may comprise more than one patient.

(See text for the explanation of the arrow in the Bland & Altman plot)

How can cumulative probability plots be used to compare progression scores between treatment arms ?

Probability plots are also useful to visually compare the distributions of two (or more) treatment arms in a clinical trial. Figure 4 shows the probability plots of the two treatment arms of the COBRA trial. COBRA combination therapy was shown to be significantly better than SSZ monotherapy in slowing one-year progression. The plots immediately show that the treatment groups differ with respect to radiographic progression. In the COBRA trial the curve representing the combination therapy group lies closer to the X-axis than that representing the monotherapy group, along the entire range of change scores, except for the scores close to - or equal to - zero. It is also obvious that the distribution of the monotherapy group includes higher absolute change scores, as compared to the distribution of combination therapy group. At last, the cumulative probability curves are not entirely "smooth", and the space between both curves, which is an indication for the treatment contrast, varies along the axis of cumulative probability. This irregularity is important if one realises that binomial cut-off levels for radiographic progression are often used to "understandably" describe the magnitude of the treatment effect. The probability curves learn that the choice of the cut-off level is relevant for the magnitude of the treatment contrast. For example, if a cut-off level of 0 Sharp-units is selected (every patient with a score >0 is considered "progressive"), there is progression in 80% of the patients in the combination group compared to 87% in the monotherapy group, resulting in a between-group contrast of only 7%. The choice of a cut-off level of 5 Sharp-units, in contrast, would adjudicate progression to 31% and 58% in the combination group and monotherapy group, respectively, with a treatment contrast of 27%. As a consequence, an optimal cut-off level (read: that provides the highest contrast) can be constructed.

Figure 4. Cumulative probability plots of individual 1-year radiographic progression scores (in Sharp-units) in 135 patients with rheumatoid arthritis who had participated in the COBRA trial (67 patients in the monotherapy group (open circles), and 68 patients in the combination therapy group (open triangles)).

What can we conclude ?

The ordinary way of presenting radiographic progression by descriptive statistics such as medians and percentiles, combined with means and standard deviations, gives rise to a loss of potentially relevant information. Probability plots can be used to visualise the phenomenon of measurement error, or to explore treatment differences in clinical trials, and may learn a lot more about the course of radiographic progression. Likely the most important advantage of probability plots over conventional means of presentation is that probability plots, unlike percentiles or Box & Whisker plots, clarify whether or not there is coherence among the data. Demonstration of data coherence may add to the credibility of a group-result if this is presented as a median. Probability plots can also be used in other outcome areas to visualize data, especially if there is a skewed distribution.

Measuring disease activity and damage in inflammatory arthritis

Patrick Verschueren, Nathalie Berghen and Pedro Machado

A previous version was coauthored by Pernille Bøyesen, Pedro Machado, Désirée van der Heijde and Mikkel Østergaard

IN-DEPTH DISCUSSION II

**Magnetic resonance imaging of synovial and bone
inflammation: a clue to what drives erosive
progression in RA**

RA is a heterogeneous disease characterised by joint inflammation (1, 2). Persistent joint inflammation can cause local bone damage, which is related to functional disability during the course of the disease (3, 4). With the introduction of new therapeutic agents and knowledge about early treatment targeting inflammation, we have experienced a major improvement in RA patient care (5-7). Moreover, considerable research efforts have been made in search of prognostic markers that would be of benefit for clinical decision-making in individual patients (8). The prognostic role of magnetic resonance imaging (MRI) has been one of the research priorities. Synovitis is considered a hallmark finding for RA and inflamed synovium visualised by MRI has been shown to be associated with bone damage (9-11). More surprisingly, MRI detected inflammation within the bone (bone marrow oedema) is frequently observed in RA patients and also predicts subsequent bone damage (11-15). This has resulted in a discussion as to whether bone erosions are a result of synovitis or bone marrow oedema (16).

What is current hypothesis regarding the pathophysiology of bone erosions in Rheumatoid Arthritis ?

The rheumatoid synovial membrane is transformed into a hypertrophic inflammatory tissue caused by influx and proliferation of macrophages, fibroblasts, T cells and B cells (17). Bone erosions typically occur at the junction of the synovial membrane and the bone, suggesting that synovitis causes erosions. Jimenez-Boj et al showed in a histological study of bone from RA patients that inflammatory synovial tissue disrupts the cortical bone barrier, directly exposing the bone marrow to inflammatory infiltrates. They found that the subchondral bone was lined with osteoclasts, as opposed to the endosteum lined with osteoblasts. These findings support that erosions are triggered from the outside by synovial inflammation (18). A later study examining the histology of MRI bone marrow oedema found localised bone marrow inflammatory infiltrates, suggesting that the bone marrow plays an active role in the inflammatory process of RA (19). Further, McQueen et al confirmed these findings and proposed MRI bone marrow oedema as a pre-erosive lesion (20). These studies underline that bone marrow oedema can occur separately, but often in conjunction with synovitis and add to the understanding of how both synovitis and bone marrow oedema can cause bone damage.

How can MRI be helpful in elucidating the pathophysiology of bone erosions in Rheumatoid Arthritis ?

MRI has been demonstrated to be a suitable tool for the evaluation of inflammation in RA. Synovitis and bone marrow oedema are frequent MRI findings in RA (12, 21-24). MRI findings of synovitis have been found to represent inflamed synovium by mini-arthroscopy and histology (25, 26). MRI findings of bone marrow oedema in RA have contributed to our understanding of the involvement of the bone marrow in the disease process (19). MRI bone marrow oedema corresponds to histological inflammatory infiltrates of the subchondral bone (19, 20). A standardised and reliable semi-quantitative scoring system of MRI synovitis and MRI bone marrow oedema has been developed in the outcome measures in RA clinical trial (OMERACT) collaboration, as part of the RA MRI score (RAMRIS) (27-30). Several studies have examined how synovitis and

bone marrow oedema assessed by MRI are associated with subsequent development of erosions. Tanaka et al showed that CRP, RF and the sum score of MRI erosions and MRI synovitis independently predicted joint damage in 114 RA patients (31). The independent contribution of MRI synovitis based on this sum score is hard to elucidate. However, MRI measured synovitis has been associated with structural bone damage across several studies (3, 9, 11, 24, 32-34). The role of the bone marrow in the development of erosions was elucidated when MRI bone marrow oedema was found to be associated with both MRI and conventional radiology (CR) measures of bone damage (13, 35). Later, two separate studies have found that MRI bone marrow oedema is independently associated with joint damage (11, 14, 15).

So far we have seen evidence that both MRI synovitis and MRI bone marrow oedema are associated with subsequent joint damage, suggesting a temporal relationship. Other studies have examined how the cumulative impact of MRI measured inflammation influences subsequent joint damage (10, 11). Conaghan et al found in a randomised controlled trial of early RA patients that the cumulative presence of MRI measured synovitis was significantly correlated with MRI erosive change (correlation coefficient of 0.42), whereas Østergaard et al showed that both baseline and 1-year time-integrated MRI synovial membrane measurements were significantly correlated with radiographic joint damage in patients with established RA (3, 24). In 55 RA patients followed for 3-years, the cumulative presence of both MRI synovitis and MRI bone marrow oedema were independently associated with progression of joint damage in a dose-dependent order (11).

To what extent can we trust the current hypothesis about the pathophysiology of bone erosions in RA ?

Before accepting the hypothesis that synovitis or bone marrow oedema are causally related to the development of bone erosions, several methodological components need to be addressed. First of all study bias, confounding and random chance, which may lead to false explanations, should be ruled out. Further, the existence of a causal relation can be established by estimating the strength of the observed association, consistency and specificity of the findings, temporal and dose-response relationship, plausibility and coherence of the results (36). The methodology of the studies presented above is sound and based on the available histological evidence it appears plausible that both synovitis and bone marrow oedema can be at the origin of subsequent bone damage. Furthermore, results also suggest a temporal and dose-dependent relationship between synovitis and/or bone marrow oedema documented on MRI and joint damage. These findings suggest that causality exists between these measures of inflammation and subsequent bone damage.

What are the practical implications of using MRI for the evaluation of patients with Rheumatoid Arthritis ?

Even though MRI has several advantages in the management of RA patients, it also has limitations. MRI scans are time-consuming, expensive and have limited availability. In addition, the scanned joint area is limited by the MRI's field of view (FOV). The FOV of one scan can include one wrist or one wrist and MCPs 2-5.

In the CIMESTRA trial, MRI bone marrow oedema was shown to be an independent predictor of CR joint damage, based on MRI assessments of the wrist as well as MRI of wrist and MCPs (14). These results suggest that one joint area may sufficiently represent inflammation. Intra-venous administration of gadolinium is commonly used for enhanced assessment of synovitis (37). Even though complications are rare, reports of nephrogenic systemic fibrosis in patients with chronic renal failure after gadolinium administration needs to be taken into consideration when ordering an MRI scan (38).

What can we conclude ?

Synovitis has traditionally been considered to trigger development of erosions in RA. However, the finding of inflammatory infiltrates in the RA bone marrow preceding erosions has led to discussion on the pathogenic mechanism of erosions. The available MRI studies, presenting assessments of synovitis and bone marrow oedema, suggest that they both are of importance to the progression of erosions in RA. Nonetheless, the modest association between synovitis, bone marrow oedema and joint damage underlines the role of other components in the development of bone destruction in RA.

Juvenile Idiopathic Arthritis

Bas Vastert, Clara Malattia, Ellen Schatorje, Alberto Martini

A previous version was coauthored by Seza Özen, Taunton Southwood, Patricia Woo, Dirk Holzinger and Johannes Roth

LEARNING OUTCOMES

- Recognise the distinctive clinical patterns of juvenile idiopathic arthritis (JIA) and its key differential diagnoses
- Describe and explain the specific inflammatory mechanisms underlying different subgroups of JIA
- Use investigations appropriately to assist the differential diagnosis, subclassification and monitoring of JIA
- Be able to provide age-appropriate disease education and counselling for children with newly diagnosed JIA and their parents
- State the importance of a multidisciplinary team approach to the treatment of JIA
- Use a safe and effective approach to drug treatment in a child with JIA
- Describe and explain complications and prognosis of different subgroups of JIA
- Describe and explain the key elements for providing an effective transitional plan for young people with JIA transferring from paediatric to adult healthcare services

1 Introduction to juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is not a single disease but a diagnosis that applies to all forms of arthritis of unknown origin, with onset prior to the 16th birthday, lasting more than 6 weeks and where other causes of arthritis have been excluded (Martini A. 2012). JIA is one of the most common physically disabling conditions of childhood, with a prevalence that varies between 16 and 150 per 100,000; about 12 000 children are affected in the UK and about 62 000 in the USA (Prakken et al, 2011*). Reported annual incidence rates of chronic childhood arthritis have ranged from less than 1 per 100,000 in Japan to more than 20 per 100,000 in Norway (Cassidy and Petty, 2005*). Relative frequency of the various JIA subtypes vary substantially according to geographic and ethnic differences (Saurenmann RK et al. Arthritis Rheum 2007): oligoarthritis, by far the most common category in Western countries is, in fact, quite rare in countries such as Costa Rica, New Zealand and South Africa or India, where polyarthritis seems to be predominant.

JIA is a diagnosis of exclusion based on a careful history taking, a thorough physical examination, and laboratory tests meant to rule out other known causes of arthritis in childhood, as reported in box 1.

For the experienced paediatric rheumatologist, the patient with JIA often presents with an almost instantly recognisable pattern of symptoms and physical findings, even during the first few weeks of illness, and very few investigations may be required. An inexperienced clinician, however, may rely heavily on inappropriate investigations in an attempt to confirm or exclude JIA. The lack of timely detection of JIA and delay in treatment is likely to adversely affect the course and outcome of the disease.

Box 1 Differential diagnosis of juvenile idiopathic arthritis

A child presenting with a single inflamed joint

Septic arthritis or osteomyelitis: consider *Staphylococcus aureus*, *Haemophilus influenzae* in non-immunised individuals; *Mycobacterium tuberculosis*, *Salmonella* spp in sickle cell disease; *Pseudomonas* spp in puncture wounds of the foot

- Lyme disease in areas where the disease is endemic. Serology indicated if the history and clinical features are suggestive
- Reactive arthritis: secondary to extra-articular bacterial (eg, streptococcal, enteric bacteria) or viral infections (eg, hepatitis B, parvovirus, Epstein–Barr virus (EBV), varicella, rubella). ‘Irritable hip’ may be a form of reactive arthritis
- Haemarthrosis: secondary to trauma (including non-accidental) or bleeding diathesis
- Malignancy: acute lymphoblastic leukaemia is the most common
- Trauma
- Solid tumour

A child presenting with more than one inflamed joint

- Connective tissue diseases: systemic lupus erythematosus (SLE), juvenile dermatomyositis, sarcoidosis, Sjögren syndrome, mixed connective tissue disease (MCTD), Henoch–Schönlein purpura
- Reactive arthritis: secondary to bacterial or viral infections
- Lyme disease
- Malignancy: leukaemia or lymphoma should always be considered in a child who has suggestive clinical and laboratory features such as cytopenia
- Immunodeficiency-associated arthritis
- Inflammatory bowel disease-associated arthritis
- Other: chronic recurrent multifocal osteomyelitis, cryopyrin-associated periodic syndromes (CAPS), including chronic infantile neurological cutaneous and arthritis syndrome (CINCA), familial Mediterranean fever

A child presenting with prominent systemic features

- Connective tissue diseases: SLE, MCTD, Kawasaki disease, other systemic vasculitis syndromes
- Neoplasia: especially neuroblastoma in a young child
- Infection: bacterial (streptococcal, including acute rheumatic fever, tuberculosis, Gonococcus, Lyme disease, and Brucella), viral (EBV and hepatitis B) or parasitic (malaria)
- Inflammatory bowel disease
- Autoinflammatory disorders: these are characterised by recurrent attacks of fever and arthralgia or arthritis often accompanied by abdominal pains and rash. Many are the result of gene mutations and so present from birth or at a very early age. Specific genetic tests are indicated if the clinical features are suggestive. Examples are familial Mediterranean fever, hyper-IgD syndrome, CAPS including CINCA syndrome (CINCA/NOMID), tumour necrosis factor receptor associated syndromes (TRAPS) and pharyngitis fever arthritis periodic fever (PFAPA), familial Mediterranean fever

A child presenting with musculoskeletal pain in the absence of swelling

- Hip disease: Perthes disease or avascular necrosis of the femoral head, slipped upper femoral epiphysis
- Benign hypermobility syndrome
- Inherited metabolic diseases: Gaucher disease, Scheie disease
- Osteochondroses: Osgood–Schlatter disease, Scheuermann disease
- Idiopathic pain syndromes: nocturnal ‘growing’ pains, complex regional pain syndrome, fibromyalgia
- Solid tumours

JIA is an internationally accepted umbrella term that has replaced all previously used nomenclatures, including juvenile rheumatoid arthritis and juvenile chronic arthritis. JIA is an exclusion diagnosis that encompasses all

forms of arthritis that begin before the age of 16 years, persist for more than 6 weeks and are of unknown origin (Box 2).

Box 2 Criteria for the diagnosis of juvenile idiopathic arthritis

All three conditions must be met

- Arthritis persisting for longer than 6 weeks
- Arthritis beginning before 16 years of age
- Exclusion of other conditions associated with or mimicking arthritis

This heterogeneous group of chronic arthritides has been classified on clinical and laboratory grounds to try to identify homogeneous, mutually exclusive categories primarily suitable for aetiopathogenic studies (box 3). By convention, classification is based on the symptoms presented during the first 6 months of disease (Petty et al, 2001*). This classification, which is an evolving process, has been recently criticised since there is evidence that while some categories identify quite definite disease entities, others represent heterogeneous conditions (Duffy et al, 2005*; Martini, 2012*).

Box 3 Second revision of the proposal for the development of classification criteria for juvenile idiopathic arthritis

Primary definition of juvenile idiopathic arthritis (JIA): definite arthritis of unknown aetiology that begins before the 16th birthday and persists for at least 6 weeks

Categories of JIA

1. Systemic arthritis
2. Oligoarthritis: - Persistent oligoarthritis
- Extended oligoarthritis
3. Polyarthritis (rheumatoid factor positive)
4. Polyarthritis (rheumatoid factor negative)
5. Psoriatic arthritis
6. Enthesitis-related arthritis
7. Undifferentiated arthritis

2 Clinical features of JIA

2.1 Symptoms of JIA

Many affected children present during their preschool or early school years, and often the patients have difficulty in describing their symptoms. The onset of arthritis in JIA is more often insidious than acute and pain is an inconsistently reported symptom of JIA. Parents are likely to note limping, particularly if the lower limb joints are affected, or joint swelling if one or more large peripheral joints are involved, such as the knee (the most commonly affected joint), ankle or wrist. It is more rare for children to present with isolated small joint (finger or toe) arthritis or axial joint involvement (i.e. involvement of the shoulder, hip or spine). Joint stiffness in the morning or gelling after prolonged rest occurs frequently in the active phase of the disease. Stiffness improves with movement, and is helped by a warm bath or shower. Duration of morning stiffness, limping and difficulty with function in the mornings and after naps provides a useful parameter for monitoring disease activity. The extra-articular features of JIA are mentioned in the description of the different JIA categories.

2.2 Physical findings in JIA

Joint involvement may be monoarticular, oligoarticular, polyarticular, symmetric or asymmetric depending on the specific JIA category. Though any joint can be affected, large joints such as the knee and the ankle are commonly involved in oligoarthritis and are responsible for the common complaint of limping; small joints of the hands and feet are usually involved in polyarticular-onset and systemic disease. The temporo-mandibular joint (TMJ) should be carefully examined, given the high prevalence of TMJ disease at the time of diagnosis. Early detection of TMJ inflammation is crucial to prevent severe mandibular growth abnormalities and condyle deformities. The clinical skills of paediatric musculoskeletal examination require knowledge of the development of the musculoskeletal system and of the joint excursion ranges in different ages. Examination of all children and adolescents should take place in an appropriately decorated, secure, sensitive and confidential environment. It is important to recognise that, particularly for young children, completing a thorough physical examination may require time and more than one attempt. Although it is time consuming, engaging the child in play may assist both initial and subsequent examinations. It is surprising how much functional musculoskeletal evaluation can be achieved by astute observation of the child at play (table 1).

Table 1 The functional musculoskeletal examination

Position	Musculoskeletal features examined
Sitting cross-legged	Hip abduction, external rotation and flexion, knee flexion
Rising to stand straight	Leg extension, back extension, lower limb muscle power
Bending forward	Anterior spinal curvature, scoliosis
Removing shoes/socks	Hip/knee flexion, hand and wrist function
Removing top	Shoulder and elbow range of movement
Walking normally	Gait phases: stance, push off, swing, heel strike
Tiptoe walking	Toe extension, ankle plantar flexion, muscle power
Heel walking	Ankle dorsiflexion, knee extension, pain at entheses
Hands pronated, arms extended	Elbow extension, shoulder power
Making a fist	Finger flexion
The 'hands praying' position	Wrist extension, elbow flexion, finger extension
Arms up above the head, reaching	Shoulder flexion
Looking over each shoulder	Cervical spine rotation

2.3 Normal variations in skeletal development

Children do not grow in a straight line, either in their skeletal alignment or their growth velocity. Minor degrees of asymmetry can often be detected on examination, most commonly in the size of the feet and length of the legs. It is important to be aware that babies are normally born with a varus knee angle which gradually straightens with age to neutral alignment between 18 months and 2 years of age. Further normal growth usually results in a progressive change in knee alignment to a valgus position, which is maximal between 5 and 7 years of age (up to 15°), resulting in an intermalleolar distance at the ankles of up to 5 cm. In this context, moderate degrees of knee varus (bow legs) or valgus (knock knee) are common and usually normal. Another common variation of normal is the posture of the foot. Most babies do not have an appreciable medial longitudinal foot arch, or a stable hindfoot position, at birth. This results in marked ankle valgus and a 'flat foot' (pes planus), which is obvious once the infant begins walking. If a child of about 10 years or over continues to have pes planus and ankle valgus (over pronation) in association with lower limb, back or generalised musculoskeletal pain, a diagnosis of hypermobility should be considered. In general, children are more flexible than adults, and the range of normal joint movement in children is measurably greater.

2.4 Effect of arthritis on the growing skeleton

An important source of damage in JIA is represented by effects of the inflammatory process and muscle atrophy, misalignment and muscle contracture on the development of bone and joint. In a growing skeleton, joint

contractures secondary to persistent synovitis may lead to deformity. For example joint contracture of the knee leads to a valgus deformity and, if the involvement is unilateral, to leg length discrepancy secondary to bone overgrowth in the affected side. These anomalies, that represented a major challenge in the past, can now be effectively prevented by intra-articular steroid injections that induce a rapid relief of inflammation, restore function and therefore interrupt the vicious circle leading to deformity .

Indeed, local growth disturbances occur at sites of inflammation, resulting in either overgrowth (possibly related to inflammation-induced increased vascularisation and growth factor release) or undergrowth (secondary to growth centre damage or premature fusion of epiphyseal plates) of the juxta-articular bone extremities. Other anomalies in growth and morphogenesis of skeletal segments include micrognathia and developmental anomalies of the hips. The management of JIA should therefore be aimed at treating progressive, erosive disease and also at preventing bone and joint deformities due to the effect of articular inflammation on the growing skeleton.

Chronic inflammation may affect linear growth, and stunted growth was one of the features described by GF Still in his initial description of systemic JIA (sJIA). However, especially in systemic onset JIA we should also consider growth retardation as a consequence of prolonged steroid therapy. Indeed, one of the main side effects of steroid therapy in paediatrics is the inhibition of growth. In every child, and more frequently in those receiving steroid therapy, growth and weight centiles have therefore to be checked periodically.

3 Clinical patterns of JIA

3.1 Systemic arthritis

sJIA is characterized by the presence of a quotidian, high spiking fever (figure 1) associated with systemic features such as an evanescent, non-fixed, erythematous rash (figure 2), hepatosplenomegaly, generalised lymphadenopathy and serositis. Myalgias and abdominal pain may be intense during fever peaks. Arthritis is more often symmetrical and polyarticular; it may be absent at the onset and develop during the disease course. Laboratory examinations show a prominent inflammatory response characterised by leucocytosis (with neutrophilia), high erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) concentration, hyperferritinaemia, very high serum levels of S100A8/S100A9 and S100A12 and thrombocytosis. A microcytic anaemia is common, as is ferritinaemia. The differential diagnosis of sJIA can be difficult, especially at presentation, and includes bacterial or viral infection, malignancy and other rheumatic diseases.

Figure 1 Temperature chart showing the characteristic quotidian fever of systemic arthritis.

Figure 2 Typical, erythematous and evanescent rash of systemic arthritis.

The disease does not show a preferential age at onset and occurs as often in boys as in girls. It accounts for 10–15% of children with JIA and is considered the equivalent of ‘adult-onset Still's disease’.

The marked activation of the innate immune system has led to the suggestion that sJIA is a polygenic autoinflammatory disease. It probably represents a syndrome, the common endpoint of several different diseases all causing marked and persistent activation of the innate immune system (Martini A. 2012).

In about half of patients the disease is monocyclic or is characterised by relapses followed by intervals of remission. The long-term prognosis of these patients is usually good. In the other half of patients the disease follows an unremitting course; in many cases systemic symptoms eventually resolve, leaving chronic arthritis as the major long-term problem.

For unknown reasons, children with sJIA are particularly susceptible to developing a life-threatening complication, called macrophage activation syndrome (MAS), occurring in about 5–8% of patients. MAS is a form of reactive haemophagocytic lymphohistiocytosis and is characterised by the sudden onset of sustained fever, pancytopenia, hepatomegaly, liver insufficiency, a coagulopathy with haemorrhagic manifestations and neurological symptoms. Laboratory features include raised transaminases and triglycerides and markedly increased ferritin concentrations. Fibrin degradation products are present and hypofibrinogenaemia is induced by diffuse intravascular coagulation. The presence of phagocytosis of haematopoietic cells by macrophages in the bone marrow is common. MAS is a severe condition that can pursue a rapidly fatal course. Prompt recognition of its clinical and laboratory features and immediate therapeutic intervention are, therefore imperative. Classification criteria for the timely diagnosis of MAS complicating sJIA have recently been produced. (Ravelli A 2016). The conventional therapeutic approach to MAS in sJIA is to administer intravenous methylprednisolone pulse therapy (in high divided doses) in association with cyclosporine. This approach is usually able to control this complication if the diagnosis is precocious and the treatment promptly instituted. Understanding the balance of cytokines in the cytokine storm of MAS is crucial to the effort of utilizing the available cytokine-targeted biologic therapies. The rapid and dramatic benefits seen with the use of (high dosed) anakinra, is generating substantial enthusiasm for treating sJIA associated MAS with IL-1 blockade.

3.2 Oligoarthritis

Oligoarthritis is defined as arthritis that affects four joints or fewer during the first 6 months of disease, in the absence of features (psoriasis, rheumatoid factor (RF) positivity, high spiking fever, etc) that qualify for other categories. In Western countries, where oligoarthritis represents up to 50% of all JIA cases, the large majority of patients belong to a well-defined disease entity seen only in children and characterised by several common features: an asymmetrical arthritis, an early onset (before 6 years of age), a female predilection, positive antinuclear antibodies (ANAs), a high risk for developing chronic iridocyclitis and consistent human leucocyte antigen (HLA) associations (HLA-DRB1*08, in particular).

The International League of Associations for Rheumatology (ILAR) classification distinguishes two categories: persistent oligoarthritis, in which the disease remains confined to four joints or fewer, and extended oligoarthritis, in which arthritis extend to more than four joints after the first 6 months of disease. It has been shown however that ANA-positive patients with persistent or with extended oligoarthritis share the same features, strongly suggesting that they represent the same disease differing just in the spread of arthritis.

Involvement of an upper limb joint and higher sedimentation rate at onset have been identified as predictors for evolution to the extended phenotype, which may occur in up to 50% of patients. Oligoarthritis is predominantly a disease of the lower limbs, with the knee joint being most commonly affected (figure 3), followed by the ankles. In about 30–50% of cases a single joint is involved at presentation. Acute phase reactants are usually normal or moderately increased; although in some instances ESR may be quite high.

While children with persistent oligoarthritis have in general a good long-term articular outcome, those with extended oligoarthritis may have a less favourable long-term prognosis. Both subtypes can however be complicated by (severe) anterior uveitis, a disease manifestation developing in about one-third of patients.

Figure 3 Persistent oligoarthritis in a 3-year-old girl.

JIA associated uveitis is a chronic, non-granulomatous, anterior uveitis that involves the iris and the ciliary body (iridocyclitis) and can cause severe visual impairment. In contrast with the painful, acute iridocyclitis that can be observed in enthesitis-related arthritis (ERA), it is asymptomatic. One or both eyes may be affected. In most cases it occurs at the time of diagnosis or shortly thereafter, although in a minority of patients (<10%) it can precede the onset of arthritis. Most children develop iridocyclitis within 5–7 years after onset of arthritis. The course of iridocyclitis may be relapsing or chronic and does not parallel the course of the arthritis. Children with iridocyclitis are at risk of developing serious complications, which include posterior synechiae, band keratopathy, cataract and glaucoma. The outcome of iridocyclitis relies very much on early diagnosis and treatment, therefore, since iridocyclitis is asymptomatic at onset, it is mandatory to screen children with oligoarthritis every 3 months by slit-lamp examination.

3.3 Polyarthritis (RF negative)

RF-negative polyarthritis is defined as an arthritis that affects five or more joints during the first 6 months of disease in the absence of RF (figure 4). Its frequency varies according to geographical origin: polyarthritis accounts for approximately 15-20% of JIA patients in British and Canadian studies while its percentage was significantly higher in other racial groups such as East Indian (61%) or native North American Indian (64%). It is a heterogeneous category. At least two distinct clinical phenotypes can be identified: (a) a form that is closely similar to adult-onset, RF-negative rheumatoid arthritis (RA) and is characterised by overt symmetrical synovitis of large and small joints, onset at school age, raised ESR, negative ANAs and variable outcome; (b) a second form that resembles ANA-positive, early-onset oligoarthritis in any respect (early age at onset, ANA positivity, asymmetrical arthritis, female predominance, increased incidence of chronic iridocyclitis, association with HLA-DRB1*08) except the number of joints involved during the first 6 months of disease. The strong similarities between this second subset and ANA-positive, early-onset oligoarthritis led to the suggestion that they are the same disease, the former representing a rapid arthritis spread in the latter. In keeping with this hypothesis, gene expression studies in oligoarticular and polyarticular JIA have shown that patients with early-onset arthritis (≤ 6 years) are characterised by a B cell signature independently of the number of joints involved. The long-term prognosis of ANA-positive, early-onset, RF-negative polyarthritis is worse than that of persistent oligoarthritis and similar to that of extended oligoarthritis. ANA-positive patients carry a high risk of chronic iridocyclitis and have to be checked every 3 months by slit-lamp examination.

Figure 4 Symmetrical arthritis in a young child with polyarthritis (rheumatoid factor negative). Parental/guardian consent obtained.

3.4 Polyarthritis (RF positive)

RF positive polyarthritis is defined as the involvement of five or more joints during the first 6 months of disease and by the presence of positive rheumatoid factor (RF) on two occasions at least three months apart during the first 6 months of disease. It is considered the paediatric counterpart of adult RF-positive rheumatoid arthritis (RA) and shares a similar clinical phenotype, serology and immunogenetic profile. The shared epitope (SE) present in some HLA-DR4, DR1 and DR14 alleles is associated with an increased risk for both adult RA and RF positive JIA. In Europe it accounts for a small ($\leq 5\%$) percentage of patients with JIA. It primarily affects girls and usually presents in late childhood or adolescence with a symmetric polyarthritis affecting principally wrists and the small joints of the hands and feet. It can be rapidly progressive and destructive. Rheumatoid nodules have been reported in about a third of patients in the first year of disease. Nodules which are firm, mobile and non-tender, often occur on bony prominences and pressure points such as distal to the olecranon, on flexor tendon sheaths and on the soles of the feet. ESR and C-reactive protein are elevated and a moderate normochromic and normocytic anaemia is often associated. It is the only JIA category in which antibodies to cyclic citrullinated peptides (anti-CCP) are found. Aggressive medical treatment of RF-positive polyarthritis is warranted because of its almost uniformly poor prognosis. Patients with RF-positive polyarthritis, in fact, have the lowest remission rate off-medication among children with chronic arthritis monitored for 10 years (Wallace CA et al. 2005). Radiological changes occur earlier and more frequently in RF-positive polyarthritis than in the other JIA categories and are observed particularly in the hands and feet.

3.5 Psoriatic arthritis (JPsA)

The diagnosis of juvenile psoriatic arthritis (PsA) by ILAR criteria requires the simultaneous presence of arthritis and a typical psoriatic rash or, if the latter is absent, the presence of arthritis and any two of the following: family history of psoriasis in a first-degree relative (figure 5); dactylitis (swelling of one or more digits that extends beyond the joint margins) and nail pitting.

Figure 5: Psoriatic arthritis.

Psoriatic arthritis is another heterogeneous JIA category representing about 5–10% of all JIA cases. Younger children, most commonly female and with positive ANA test, tend to develop asymmetric oligoarthritis and have a high risk of chronic iridocyclitis. This subgroup appears very similar to the early-onset oligoarticular JIA, the main difference being that patients with JPsA tend in some series to develop more frequently a polyarticular course. By contrast, older-onset JPsA patients exhibit a gender ratio closer to 1:1, with a tendency to enthesitis and to develop sacroiliitis during follow-up, similar to several adult patients with psoriatic arthritis who share features with spondyloarthropathies. The ILAR classification criteria for PsA, in which patients with enthesitis are by definition excluded, limit the identification of those patients who have a form of PsA similar to that seen in adults.

In children with JPsA, dactylitis is observed in 20% to 40% of patients, its swelling is typically uniform, giving the appearance of a "sausage digit". Ultrasound (US) examination shows tenosynovitis of the digit flexor tendons as a dominant finding, with or without synovitis in the adjacent joints. Subperiosteal new bone growth can also increase the thickness of the digit. Overt psoriasis occurs in 40% to 60% of patients with JPsA usually as the classic vulgaris form. As in other JIA subsets, young patients with ANA positivity are at highest risk of chronic uveitis, and periodic screening with slit-lamp should be performed. The long term prognosis of PsA is not well defined, due to its heterogeneity and the lack of available information.

3.6 Enthesitis-related arthritis

Enthesitis-related arthritis accounts for about 5–10% of JIA cases and is an undifferentiated spondyloarthritis. It typically begins after the age of 6 years and affects boys more often than girls. Most patients are HLA-B27 positive. Arthritis commonly affects the joints of the lower extremities and is usually associated to enthesitis (inflammation of the point where a tendon, ligament or fascia inserts into the bone). The most common sites of enthesitis are the calcaneal insertions of the Achilles tendon, plantar fascia, and tarsal area. In contrast to the other JIA categories, hip involvement is frequent at disease presentation. Symptoms of sacroiliitis and spine involvement are uncommon at presentation. Although it may be a precursor to ankylosing spondylitis, it is not known how many children with ERA progress to ankylosing spondylitis during their adult years. Uveitis may also affect these JIA patients, but in ERA it tends to be symptomatic, presenting with red eyes, photophobia and pain. A family history of similarly affected relatives is often positive.

3.7 Undifferentiated arthritis

Undifferentiated arthritis is not a defined entity, but a category that includes patients who do not fulfil inclusion criteria for any category, or fulfil the criteria for more than one category. About 10–15% of all JIA cases are included in this category.

4 Investigations in children with arthritis

Laboratory Examination

JIA is a diagnosis of exclusion and a wide range of differential diagnosis need to be ruled out. Laboratory investigations may be useful for the exclusion of other disorders (Table 2), to aid categorization of the JIA subsets, and to monitor the extent of inflammation. Immunological markers such as antinuclear antibodies (ANA) and rheumatoid factor (RF) are not specific for JIA. They, in fact, may be transiently positive after a viral illness, and may be also present in other connective tissue disorders and even in healthy children. Tests for RF, antibodies to cyclic citrullinated peptides (anti-CCP) and ANAs should be considered only after the diagnosis of JIA has been made: RF to help sub classify children with polyarthritis, and ANAs to identify a group of patients who carry a high risk of developing iridocyclitis and require a periodic slit-lamp examination. As mentioned above, ANA positivity allows to identify early-onset, ANA-positive arthritis, which represents a well-defined entity that is seen only in childhood and which is currently misclassified into several different JIA subtypes (oligoarthritis, RF-negative polyarthritis, PsA).

Hematologic abnormalities such as leukocytosis (polymorphonuclear leukocytes predominate) and thrombocytosis usually reflex the extent of the inflammatory disease. On the other hand, isolated raised lactate dehydrogenase associated to hematologic abnormalities such as leukopenia and thrombocytopenia should alert the physician to the possibility of acute lymphoblastic leukaemia.

Acute phase reactants help in monitoring disease activity and monitoring the therapeutic efficacy. It is important however to highlight that JIA patients, especially those with oligoarthritis, may have normal values at the disease onset. In the systemic and polyarticular categories, ESR and CRP are usually raised, often along with neutrophilic leucocytosis, thrombocytosis and a microcytic anaemia. Anaemia, usually secondary to chronic inflammation, can occur in all forms of JIA but is more pronounced in systemic JIA. It is characterised by a striking defect in the iron supply for erythropoiesis, while growth of erythroid colonies is normal and erythropoietin production is appropriate. These findings are consistent with the effect of IL-6 on erythropoiesis. A sudden drop of leucocyte count and platelets occurs during MAS as well as a sudden increase of transaminases and ferritin levels. Liver function tests should always be performed as a baseline screening before starting non-steroidal anti-inflammatory drugs (NSAIDs) or methotrexate and then to monitor drug-related side effects. Increases in serum levels of the immunoglobulins reflect the acute-phase response, whereas selective IgA deficiency occurred in 4% of the children.

Antistreptolysin O titres and anti-DNase B titres should be acquired to exclude acute rheumatic fever or post-streptococcal arthritis. To exclude other forms of reactive arthritis, stool cultures or serology for yersinia, salmonella, shigella, campylobacter or viral serology (Parvovirus B 19, hepatitis B, influenza, Coxsackie virus, Epstein–Barr virus, cytomegalovirus, varicella, endemic viruses) should be performed based on the clinical

history. *Borrelia burgdorferi* or brucellosis serology should be acquired to rule out Lyme disease or brucellosis if there is a history of travel in endemic areas and/or clinical suspicion.

Synovial biopsy is not indicated for the diagnosis of JIA, but may have a role in the exclusion of rare causes of joint swelling, such as neoplasia, sarcoidosis or pigmented villonodular synovitis. The inflammatory synovitis in JIA does not have specific features; macroscopically and microscopically it is similar to that seen in adult RA while the findings seen in enthesitis-related arthritis overlap with those reported in adult spondyloarthritis.

Radiologic Examination

Imaging evaluation of the child with clinical features of rheumatic disorder has an important role in excluding a wide range of differential diagnosis. Conventional radiographs (CR) is the first-step imaging modality which should be performed to exclude other causes of joint pain and swelling, such as fracture, osteocondroses, bone tumours, skeletal dysplasias, slipped upper femoral epiphysis, avascular necrosis etc. MR imaging (MRI) and musculoskeletal ultrasound (US) are encountering expanding application in the assessment of patients with chronic inflammatory arthritis. EULAR/PRES point to consider for the use of imaging in the diagnosis and management of JIA in clinical practice have been recently published. US (figure 6) and MRI are more sensitive than clinical examination in the evaluation of joint inflammation; these techniques should therefore be considered for more accurate detection of inflammation, both in diagnosis and assessing extent of joint involvement.

Figure 6 Ultrasound longitudinal scan of the hip joint of a girl aged 2 years. FH, femoral head; FN, femoral neck; GP, growth plate; JE, joint effusion; SH, synovial hypertrophy.

US has a great potential amongst the paediatric rheumatologists; it is non-invasive, well tolerated and it can be applied directly in the clinic. Over the last decades a great deal of effort has been done to define the normal sonographic anatomy throughout paediatric age groups, to standardize a US scanning approach (i.e., patient

position, transducer placement, and joint positioning) and provide definitions and grading of joint pathological findings. These steps are essential to consider US as a valuable imaging tool for diagnosis and monitoring of disease course and treatment efficacy.

Since no specific MRI signature for JIA has yet been described, MRI is not recommended as a first line investigation in every patient suffering from recent-onset arthritis, but should be used when there is clinical diagnostic doubt to rule out other intra-articular pathologies mimicking JIA, such as pigmented villo-nodular synovitis, synovial haemangioma or lipoma arborescens, which all have recognisable features on MR imaging. In JIA MR imaging may be of particular benefit over routine clinical evaluation when assessing disease activity is highly challenging as for TMJ or axial skeleton. MRI has proven to be the most sensitive and specific imaging method to detect early and/or subtle sacroiliitis and for diagnosis cervical spine involvement. It allows the detection of synovial pannus at the C1-2 joints which, if persistent, potentially lead to posterior laxity of the ligamentous complex resulting in atlo axial instability and consequent risk of upper spinal cord.

More information concerning the use of imaging in the assessment of JIA have been reported in a separate chapter (see in-depth discussion I).

Table 2 Laboratory and imaging investigations in juvenile idiopathic arthritis and differential diagnosis

Investigation		Justification for investigation				
		Differential diagnosis	JIA sub-classification	JIA monitoring	Drug adverse event monitoring	
Haematology	Full blood count	Leukaemia, SLE			Several DMARDs and biological agents	
	Bone marrow examination	Leukaemia				
	ESR	Macrophage activation syndrome Core outcome variable				
Biochemistry	Liver function	Macrophage activation syndrome			NSAID and MTX	
	Muscle enzymes	JDM, overlap syndromes				
	Renal function including urine analysis	SLE with nephritis			NSAID	
	Urinary catecholamines	Neuroblastoma				
	Urinary amino and organic acids, etc.	Inherited metabolic diseases				
	ANA	SLE, JDM, overlap, other autoimmunity		Associated with risk of chronic anterior uveitis		

Immunology	RF Antibodies to CCP HLA-B27	Overlap	In RF-positive patients In enthesitis-related arthritis
	Immunoglobulins	Immune deficiency	
	<ul style="list-style-type: none"> Bacterial and viral serologies 	Reactive arthritis	Varicella titres before beginning DMARDs, biological agents
Microbiology	Skin test for TB Quantiferon		Before beginning DMARDs, biological agents or steroids
	Synovial fluid microscopy and culture	Septic arthritis	

ANA, antinuclear antibodies; DMARDs, disease-modifying antirheumatic drugs; ESR, erythrocyte sedimentation rate; HLA, human leucocyte antigen; JDM, juvenile dermatomyositis; JIA, juvenile idiopathic arthritis; MTX, methotrexate; NSAID, non-steroidal anti-inflammatory drug; RF, rheumatoid factor; SLE, systemic lupus erythematosus; TB, tuberculosis.

5 Treatment of JIA

5.1 General principles of JIA treatment

The past decade has witnessed major advances in the treatment of JIA and remission has now become a realistic goal. The main aims of these medications is to achieve complete control of the disease with normalization of physical findings and laboratory markers of inflammation, to preserve the physical and psychological integrity of the child, and to prevent any long-term consequences related to the disease or its therapy. Evidence has been provided that early diagnosis and a prompt control of inflammation improves the outcome and can prevent long-term sequelae. Whenever possible, the care of a child with JIA should be provided by an efficient operating, multidisciplinary team (boxes 4 and 5). It should be led by one or more paediatric rheumatologists working in tandem with a team of clinical experts in paediatric rehabilitation, disease education, clinical and drug monitoring, school advocacy, nutrition, family and social support, and psychology, if appropriate. In addition, the need for ready access to other paediatric specialties, such as ophthalmology, orthopaedics, maxillofacial surgery, nephrology, infectious disease and dermatology, underlines the complexity of optimal management required for these children.

Box 4 Healthcare professionals involved in the treatment of juvenile idiopathic arthritis (JIA)**Members of the paediatric rheumatology care team**

- Paediatric rheumatologist
- Paediatric nurse clinician
- Occupational therapist
- Social worker
- Psychologist, nutritionist

Members of the extended specialist team for JIA

- Ophthalmologist: detection and monitoring of uveitis
- Paediatric physiotherapist: to keep JIA patients active, promote regular exercise and a healthy lifestyle
- Orthopaedic surgeon: surgical interventions to aid rehabilitation, correction of local growth deformity
- Dentist: for diagnosis and management of TMJ involvement
- Orthotist/podiatrist: correction of pes planus and other foot deformities

NSAIDs and intra-articular steroids

Oral non-steroidal anti-inflammatory drugs (NSAIDs) represent the initial treatment for the majority of JIA patients. In contrast to adults, just a few NSAIDs are approved for use in children. The most common include naproxen, ibuprofen, indomethacin and meloxicam, an inhibitor of both cyclo-oxygenase 1 (COX1) and COX2.

Salicylates have been replaced by NSAIDs in paediatric practice because of the association of aspirin with Reye syndrome and greater frequency of liver function abnormalities. NSAIDs are used in higher doses, relative to body weight, than in adults because children have increased rates of metabolism and renal excretion. NSAID are generally well tolerated and unlike adults fewer side-effects are reported. They include abdominal pain (usually minimised by taking the NSAID with food), and, rarely, bronchospasm (mild asthma is not a contraindication to the use of NSAIDs in children). Naproxen has the additional risk of inducing pseudo-porphyrria. However, most patients need better control of inflammation than can be accomplished with NSAIDs alone. Intra-articular steroid injections are commonly indicated at disease onset or during disease course since their quick effectiveness is pivotal in the prevention of deformities-e.g. valgus knee secondary to joint contractures, which represents an important source of damage in JIA. The long-acting steroid triamcinolone hexacetonide is used worldwide since its induced remission lasts much longer compared to other steroids. To inject smaller joints and those not easily reached, it is advised however to use a more soluble corticosteroid preparation such as methylprednisolone acetate. The procedure can be performed in an ambulatory care setting using local anaesthesia, with or without conscious sedation. Younger children, or those candidate to multiple injections, require general anaesthesia/sedation. Ultrasound guidance allows an accurate placement of the needle within the joint space thus reducing the risk of side effects and maximizing the efficacy of the procedure. The most common adverse effect is subcutaneous atrophy at the site of injection, which is caused by the delivery of the

steroid preparation out of the joint space. This complication, that can usually be avoided with a careful injection technique, may resolve with time although it can persist in some patients.

DMARDS

Patients who do not respond effectively to these approaches need systemic therapy with second line agents. Methotrexate (MTX) is considered the second-line agent of choice for persistent active arthritis, due to its effectiveness and acceptable level of toxicity. Since its efficacy begins to show usually only after one to three months, a *short* course of low-dose prednisone (0.2-0.5 mg/kg/day) might be considered as a bridging agent until MTX is effective, especially in patients with severe polyarthritis.

The most common adverse events associated with methotrexate are nausea, followed by mouth sores. Other side effects include abdominal pain, raised liver enzymes, and rarely, hair loss and bone marrow suppression. Patients taking methotrexate must have monthly blood monitoring to screen for abnormal liver function and bone marrow suppression. To reduce the risk of the side effects supplementation with folic or folinic acid should be concomitant. Furthermore adolescents must refrain from drinking alcohol. It is important to realize that up to 30-40% of patients develop signs of 'intolerance' (malaise, nausea, vomiting not only shortly after taking MTX, but often already starting hours *prior* to the intake of the weekly dose) after prolonged use of MTX. This can be difficult to manage, and can result in change of the DMARD or even to escalation of the therapy to biologics in a subset of patients.

Although recent trials have shown the efficacy of leflunomide in polyarticular JIA, clinical experience of treatment with leflunomide in JIA is still limited. This drug may be an alternative for MTX, particularly for patients who develop intolerance or major side effects to MTX.

Overall MTX is effective in about 70% of children with polyarthritis. For those unresponsive or intolerant to conventional antirheumatic agents, the introduction of biological medications should be considered.

Biologicals

The soluble TNF α receptor, etanercept, was the first biologic to be registered for the treatment of children (more than 2 years old) with polyarticular JIA based on a randomized, double-blind withdrawal study comparing Etanercept to placebo (Lovell et al, 2003*). In the open label phase, sustained effectiveness and long term safety of Etanercept were demonstrated. A synergic effect between Etanercept and Methotrexate has also been suggested. Etanercept is indicated for patients with polyarthritis/extended oligoarthritis whose disease is not adequately controlled with methotrexate or who are intolerant to it. Etanercept binds to circulating TNF- α , preventing its interaction with the cell surface receptor and the subsequent inflammatory response. It is administrated at the dose of 0.8 mg/kg/week or 0.4 mg/kg twice weekly subcutaneously (max = 50 mg/week), and its initial clinical effect usually manifests in two-three weeks. Regular (1–3 months) monitoring of blood

counts and chemistry studies are recommended. Long-term follow-up registries for use of etanercept in JIA show tolerable side effects (Shakoor et al, 2002). Since cases of reactivated tuberculosis have been reported during treatment with TNF inhibitors, all children must be negative for tuberculosis tests before starting TNF α blocking agents.

Subsequently, others biological agents have been registered for the use in JIA. In a randomised double-blinded, placebo-controlled withdrawal study, adalimumab, a fully humanised monoclonal antibody to TNF α , showed a good efficacy in children with polyarticular JIA in combination with methotrexate or alone (Lovell DJ et al N Engl J Med 2008). Adalimumab was approved by FDA for treatment of polyarticular subtype (children equal or more than 4 years old, recently modified to > 2 years of age) in 2008. Adalimumab is a fully humanized monoclonal IgG1 antibody against TNF- α that acts binding both soluble and membrane bound TNF- α . It is administered subcutaneously at a dose of 24 mg/m² every other week. Also for Adalimumab, association with Methotrexate seems to result in increased efficacy. As with other biological agents, the occurrence of (neutralising) anti-Adalimumab antibodies is described and can be considered an early marker associated to a poor clinical response. In contrast to Etanercept, Adalimumab appears to be efficacious for the treatment of JIA-related uveitis, and shows a better efficacy in maintaining remission in chronic anterior JIA-associated uveitis.

Infliximab is a chimeric monoclonal antibody directed against TNF- α in its soluble and membrane-bound forms, leading to TNF- α neutralisation and to antibody-dependent cytotoxicity of TNF- α producing cells. In 2007, a multicentre randomized double-blind placebo-controlled trial suggested efficacy of Infliximab (3mg/Kg) in polyarticular subtype, but primary end point was not significantly different from placebo, so Infliximab was not approved by FDA for JIA. The author's explanation in the publication was that probably children clear the drug more rapidly than adults, making the dosage of 3 mg/kg insufficient. Currently, doses of 6 mg/kg are suggested in children. Tolerability of Infliximab infusion is a major concern, because there is a relevant risk of infusion-related reactions, development of antinuclear antibodies (ANA) and of neutralising human anti-chimeric antibodies (HACA). Concurrent administration of MTX can help to prevent development of HACAs that may cause a higher clearance of Infliximab. HACAs seem also to be related with a higher rate of infusion-related reactions. Finally, evidence has been provided on the efficacy of Infliximab in treating JIA-related uveitis.

Golimumab is a fully humanized monoclonal antibody to soluble and transmembranous TNF- α . A phase III multicentre, open-label trial, with the purpose of evaluating the pharmacokinetics of Golimumab administered intravenously in polyarticular JIA is ongoing currently.

Certolizumab pegol is a pegylated anti-TNF- α inhibitor. Pegylation enhances the half-life of the drug and allows a 2–4-week dosing schedule. There is a clinical trial underway for the use of certolizumab in children with JIA.

T-cells play a central role in starting the inflammatory process in JIA. Several studies on monoclonal T cell-depleting antibodies were disappointing, failing to prove sustained clinical improvement or showing severe side

effects. Also interactions between molecules expressed on the surface of T cells and on antigen-presenting cells are involved in the immune response. Targeting lymphocyte activation and cellular functions may be an alternative approach for the management of JIA, in particular refractory polyarticular subtype that shows inadequate response to other therapies, including one or more anti-TNF agents. Abatacept, CTLA-4 Ig, is a soluble fusion protein that selectively modulates the CD80/CD86:CD28 co-stimulatory signal for T-cell activation during antigen presentation. Its efficacy in the treatment of children with polyarticular JIA subtype has been demonstrated in a randomized controlled trial. Abatacept is an approved therapeutic option for patients with polyarthritis who are resistant to TNF α -inhibitors. It is administered via 30 minute intravenous infusion at a dose of 10 mg/kg every 28 days.

As outlined, JIA is clearly not a single disease, and therefore different therapeutic approaches should be followed for the different subtypes. This holds particularly true for systemic JIA vs other JIA subtypes. Data from literature have demonstrated that for example anti-TNF α therapy is less effective in patients with sJIA. These clinical observations, along with increased insight in the last 15 years on the pathophysiological mechanisms, underscoring a major pathogenic role for the IL-1 and IL-6 pathways in sJIA, have subsequently directed biologic therapy for sJIA.

IL-1 is a pro-inflammatory cytokine and is produced by monocytes, macrophages and dendritic cells. IL-1 activity is physiologically controlled by the soluble IL-1 receptor antagonist (IL-1RA). In patients with chronic inflammatory arthritis, IL-1 stimulates production of inflammatory mediators by synoviocytes and chondrocytes, leading to cartilage destruction and bone erosions.

The discovery of the important role of IL-1 came from the rather serendipitous observation of the efficacy of anakinra, an IL-1 inhibitor which is the recombinant version of the naturally occurring soluble IL-1 receptor antagonist (IL-1 Ra) (Pascual V et al 2005). Anakinra binds to the IL-1 receptor on cell surfaces preventing its interaction with IL-1 and subsequent cell signalling. Due to his short half-life, Anakinra is administered in daily subcutaneous injection (1-2 mg/kg/day, max = 100 mg). Since the first description of its efficacy in sJIA, it has become apparent that the response to IL-1 blockade can be variable. In fact, two subsets of sJIA can be identified ,according to patient response to anakinra (Gattorno M Arthritis Rheum 2008). One (accounting for about 50% of patients) with a dramatic, complete response to IL-1 blockade (similar to that observed in cryopyrin-associated autoinflammatory syndromes) with complete normalization of clinical as well as laboratory features in a few days. The other resistant to treatment or with an intermediate response; in general in these patients systemic features respond well to therapy while synovitis persists. Compared to patients who had an incomplete response or no response, complete responders had a lower number of active joints and an increased absolute neutrophil count. There is increasing evidence that the early use of anakinra in sJIA is associated with a higher response rate (Vastert et al, Arthritis Rheum, 2014).

More recently canakinumab, a monoclonal antibody against IL-1, has been approved for the treatment of sJIA. Canakinumab is a fully human anti-IL-1 β monoclonal antibody that blocks selectively IL-1 β . The long half-life of Canakinumab justifies the subcutaneous administration every 4 weeks in sJIA (4 mg/kg, max 300 mg). Two randomized, placebo controlled trials have demonstrated efficacy of Canakinumab in children with sJIA and active systemic features (Ruperto N et al. N Engl J Med 2012).

In the 1990s, several laboratory studies led to the hypothesis that systemic JIA is an IL-6 driven disease (De Benedetti et al, 1994). This hypothesis was confirmed ten years later by a double-blind controlled study with a withdrawal design which showed the efficacy of tocilizumab, a monoclonal antibody against the IL-6 soluble receptor (sIL-6R), in 56 patients with sJIA (Yokota et al, 2005). More recently a multicentre double-blind placebo-controlled trial (De Benedetti et al, N Engl J Med, 2012) has confirmed the marked efficacy of tocilizumab which has been approved by the Food and Drug Administration and European Medicines Agency for patients > 2 years with persistently active sJIA. Tocilizumab is administered at a dose of 8 mg/kg (children < 30 kg: 12 mg/Kg) every 2 weeks, via intravenous infusion. In addition to its efficacy in sJIA, the efficacy and safety of the interleukin-6 receptor inhibitor (given intravenously every 4 weeks) for the treatment of patients with polyarticular-course JIA has been recently demonstrated in a randomised, double blind withdrawal trial (Brunner et al, Ann Rheum Dis 2015).

Box 5 Drug treatment

Non-steroidal anti-inflammatory drugs

- Ibuprofen 10 mg/kg/dose four times a day
- Naproxen 10-15 mg/kg/dose twice a day

Intra-articular steroids

Triamcinolone hexacetonide

- 1 mg/kg/joint for large joints
- 0.5 mg/kg/joint for medium joints

Methotrexate

- 10–15 mg/m²/dose once weekly orally or subcutaneously

Parenteral steroids

- Methylprednisolone 10–30 mg/kg/dose daily over 1–3 days
- Prednisolone 0.2–2 mg/kg/dose once a day

TNF α drugs

Etanercept

- Given by subcutaneous injection of 0.8 mg/kg once weekly or 0.4 mg/kg twice weekly
- Outcome best when combined with weekly methotrexate

Adalimumab

- 24 mg/m²/dose every 2 weeks (max 40 mg) subcutaneously
- Outcome best when combined with weekly methotrexate

T-cell costimulation modulator

Abatacept

- Given by intravenous infusion of 10 mg/kg every 28 days
- Outcome best when combined with weekly methotrexate

IL-1 drugs**Anakinra**

- Daily subcutaneous injection of 1–2 mg/kg/dose

Canakinumab

- 2–4 mg/kg/ every 4 weeks (max 150 mg) subcutaneously

IL-6 drugs**Tocilizumab**

- <30 kg, 12 mg/kg; >30 kg, 8 mg/kg every 2 weeks intravenously

Management of Chronic iridocyclitis

Anterior uveitis, that involves the iris and the ciliary body (iridocyclitis), is a characteristic complication of JIA and occurs with much higher frequency in ANA positive patients. The onset is insidious and often entirely asymptomatic. The course may be relapsing or chronic and does not parallel the clinical course of arthritis. Topical steroids associated with mydriatics are sufficient to control inflammation in a substantial part of the patients. In cases where inflammation does not respond to topical therapy, periocular subtenon injection of steroids can be indicated. Systemic steroids (prednisone at an induction dose is 1-2 mg/kg body weight) are usually prescribed in case of vision-threatening ocular inflammation. Limited response to topical (or systemic) corticosteroids requires initiation of a second-line therapy, most commonly methotrexate. From the biologic agents, both adalimumab and infliximab have been reported to be beneficial for treating JIA-associated uveitis, whereas etanercept has been associated with the newly development of uveitis in JIA patients. For patients who have failed therapy with TNF inhibitors there is minimal data to guide subsequent management. There have been successful case reports with mycophenolate mofetil, Abatacept, and Rituximab. The efficacy of Tocilizumab for severe JIA-Associated uveitis refractory to anti-TNF therapy has been recently demonstrated in a (small) multicentre study (Calvo-Rio et al, Arthritis Rheum 2016).

Tolerability and Safety of biological agents

Skin reactions at the injection site with subcutaneously administered agents are common, in particular with anakinra. Acute infusion reactions occur especially with Infliximab and are less frequent observed with Tocilizumab and Abatacept.

Cytopenias are occasionally reported upon treatment with anti TNF- α , whereas neutropenia is a concern in patients treated with Tocilizumab. All the biologic therapies potentially increase the risk of infection, tuberculosis in particular. Screening for latent tuberculosis should be performed before the introduction of a biologic agent because the increased risk of reactivation. A potential link between anti TNF- α medication and demyelinating disorders have been suggested but not proven. A major concern with the anti TNF agents in particular is the possible increase in risk of malignancy. In 2009 a FDA reported 48 cases of malignancies in children treated with an anti-TNF agents. A large part of these patients was diagnosed with an inflammatory

bowel disease and 88% were received another immunosuppressive treatment. To date a causal relationship between malignancy and biologic therapy has not been proven.

Finally the use of biologic treatment in clinical practice has raised questions on long-term safety of these drugs. For these reason, registries for long term monitoring of patients under biologic therapies are crucial. The largest international registry for biologics in JIA is Pharmachild.

7 Prognosis and Outcome

The term JIA encompasses an heterogeneous group of disorders. Its spectrum varies from mild to severe, smouldering to rapidly progressive disease. The outcome of JIA is variable and it is difficult at the onset of the disease to predict which children will remit and which will go on to have unremitting, rapidly erosive disease with subsequent high risk of functional impairment. Although several indicators of a poor outcome have been identified, including polyarticular onset of JIA, early wrist or hip involvement, the presence of RF, persistent active disease and early radiographic changes, the prediction of disease outcome in any individual patient remains unsatisfactory.

A pronounced improvement in functional outcome has been documented in the past decades, with the proportion of patients with serious functional disability and who need of assistance or aids to manage their daily routines ranging from 2.5% to 10 %. A number of studies have shown however that adolescents with chronic disease, compared with their peers, are twice as likely to be unemployed, have lower health status and be more socially isolated. Although there is a large variability among studies, around 30-40% of children with JIA seem to enter adult age with active disease and will need to participate in adult healthcare services, usually in rheumatology clinics (Szer et al, 2006*). The remission rate varies considerably with the JIA subtype, being the best for persistent oligoarthritis (Foster et al, 2003*). It should be emphasized, however, that most of the long-term outcome studies refer to an era in which biological agents were not available (David et al, 1994). Recent advances in therapeutics are expected to dramatically change the long-term outcome of children with JIA and significantly decrease the risk of permanent structural damage.

8 Adolescence and transition

The process of transition in healthcare is defined as a multifaceted, active process that attends to the medical, psychosocial and educational needs of adolescents as they move from child-oriented to adult-oriented lifestyles and systems. The evolution of the disease during adolescence also has an impact on the young person and requires more research. There is little doubt that the important tasks of adolescence can be delayed or curtailed by JIA and other chronic illnesses, including consolidation of identity, establishment of relationships outside the family and independence from the family, and successful vocational attainment. It is of concern that almost one-third of adolescents report frustration as being amongst their biggest problems. Adolescents with JIA are faced

with symptoms that can be difficult to relieve, activities they cannot perform and the uncertainty of daily fluctuations and long-term prognosis. Establishing realistic expectations and emotional responses is an important step in self-management. There are seven components of self-management: (1) minimising or overcoming disability (eg, through exercise, nutrition or rest); (2) establishing realistic expectations and emotional responses to the changes of circumstances caused by the disease; (3) interpreting and managing symptoms; (4) learning how to judge the effects of drugs and manage their use; (5) learning to become a good problem-solver; (6) communicating with health professionals and (7) using social resources. Special transition programmes and trained rheumatologists are needed in the field of adolescent rheumatology to deal specifically with the needs of adolescent patients and to consider the specific aspects in the pathology of JIA during further treatment since most adult rheumatologists are not familiar with the clinical differences of the distinct subgroups of JIA. A professional transitional programme should include individual transition plans, collaboration between paediatric and adult rheumatologists, primary care, paediatric and adult healthcare providers, administrative support and direct involvement of the young people themselves.

SUMMARY POINTS

- The diagnosis of juvenile idiopathic arthritis (JIA) relies on detecting typical clinical patterns, which are characterised by persistent swelling of one or more joints, beginning before the age of 16 years, without any clear cause being identified.
- A wide range of diseases may mimic the clinical features of JIA, the most serious of which include septic arthritis, osteomyelitis, neoplasia such as acute lymphoblastic leukaemia, neuroblastoma and lymphoma, and non-accidental injury.
- There are different clinical subtypes of JIA, including oligoarthritis, extended oligoarthritis, enthesitis-related arthritis, psoriatic arthritis, polyarthritis (rheumatoid factor (RF) negative), polyarthritis (RF positive) and systemic arthritis.
- Laboratory investigations may be helpful to exclude differential diagnoses which may mimic JIA, to subclassify JIA and to monitor the disease, but there are no pathognomonic investigations for the diagnosis of JIA itself.
- The provision of disease education on JIA—ancillary, age-appropriate written material, web resources and support and contact groups—is an essential component of treating the child with JIA and their family.
- Every child with JIA deserves access to a paediatric multidisciplinary team of healthcare professionals who are experienced in the management of JIA, in addition to appropriately trained paediatric rheumatologists. The multidisciplinary team should include nursing staff, physiotherapists, occupational therapists and psychologists. Extensive liaison with the child's school is an essential component of the management of the illness.
- Drug treatment for JIA usually proceeds in a stepwise escalating approach, beginning with non-steroidal anti-inflammatory drugs and intra-articular corticosteroids, with the early use of methotrexate for higher-risk JIA subgroups. Biological therapies, such as blockade of the proinflammatory cytokines, tumour necrosis factor, interleukin (IL)-1 and IL-6, are valuable for the treatment of JIA, which cannot be treated effectively with methotrexate.
- The child with JIA is at risk of a number of complications, including chronic anterior uveitis, dental decay, significant anaemia, osteoporosis and growth disturbance. Rare but life-threatening complications or adverse effects of treatment include sepsis, macrophage activation syndrome, Reye syndrome and amyloidosis.
- The young person who has, or develops, JIA during their adolescent years is particularly at risk of poor therapeutic adherence, an inability to complete the tasks of adolescence (identity, independence and vocation) and disenfranchisement from the medical system.
- Successful transitional programmes for young people with JIA include individualised transition plans, collaboration between paediatric and adult rheumatologists, primary care, paediatric and adult healthcare providers, administrative support and direct involvement of the young people themselves.

IN-DEPTH DISCUSSION I

Imaging in the assessment of juvenile idiopathic arthritis

MR imaging and musculoskeletal ultrasound are encountering expanding application in the assessment of patients with chronic inflammatory arthritis [1]. These imaging techniques, by providing additional and more sensitive information over clinical examination and conventional radiographs (CR), are promising tools for the diagnosis, prognosis and assessment of treatment efficacy in patients with juvenile idiopathic arthritis (JIA) [2].

This discussion aims at providing the current evidence to support the use of imaging in the assessment of JIA. Furthermore peculiar aspects relevant to the evaluation of growing skeleton will be discussed.

Conventional radiography

JIA is a diagnosis of exclusion and a wide range of differential diagnosis, many of which have recognisable features on imaging, need to be ruled out. CR is the first-step imaging modality which should be performed to exclude other causes of joint pain and swelling, such as trauma, osteochondroses, osteoid tumours, skeletal dysplasias, etc.

In patients with established JIA, CR remains the gold standard for the demonstration of cumulative structural damage to joints resulting from uncontrolled inflammation over time. Traditionally, the presence and extent of joint changes are assessed by visual inspection of CR to detect joint-space narrowing, bone erosions, and bone growth abnormalities. However, it is difficult to reliably determine cartilage loss in children, due to growing joint changes (i.e. cartilage thickness varies with age, ossification is incomplete etc.). Additionally, advancement of bone maturation secondary to hyperaemia, or the premature fusion of epiphyses due to damage, and the occurrence of unique radiographic abnormalities, such as disturbance of bone growth, are other factors that contribute to make the assessment of radiographic damage in JIA a real challenge.

In the past decade, a great deal of effort has been put into devising radiographic scores targeted to paediatric age group and also in the adaptation of adults methods to be used in JIA. Some of these measures have proved to be reliable and valid for capturing structural damage progression in JIA, thus supporting their use in standard clinical practice as well as their inclusion in therapeutic trials for testing the disease-modifying potential of new antirheumatic drugs [3].

Magnetic resonance

The major limit of CR is that it visualizes late and often irreversible erosive damage and it is insensitive in detecting soft tissue inflammation. MR by providing multiplanar tomographic imaging allows to simultaneously evaluate all joint components. Contrast-enhanced MR is the most sensitive imaging modality for the detection of synovial inflammation and allows a reliable differentiation of active hyper vascular pannus from the inactive fibrotic pannus. Standardised and validated scales for evaluating MR findings in JIA are now available [4]. The OMERACT rheumatoid arthritis (RA) MR synovitis score, has proven to be a promising imaging biomarker for

measuring the therapeutic response in patients with JIA. In a recent study only the ACR Pedi 90 responders showed a significant decrease in synovitis and the halting of structural damage, enhancing the need to move towards higher levels of clinical response to assess drug efficacy, and suggesting the potential of MR as a primary efficacy outcome [5]. In this perspective quantitative measurements of synovitis appear particularly promising in evaluating treatment efficacy. Dynamic contrast-enhanced MR, which analyses the time course of signal changes following gadolinium administration, and computerized measurements of synovial volumes have proved to be reliable methods to quantitatively assess disease activity, monitor treatment efficacy and predict joint destruction in JIA [6].

Although sustained synovitis was recently documented by MR in a sizable proportion of JIA patients who satisfied clinically-defined remission criteria [7], no longitudinal studies have thus far investigated whether MR detectable subclinical inflammation may end up in further joint damage and functional disability, as reported in adults with RA.

Early detection of patients who will develop erosive damage is of outstanding value to reduce the chance of further disability. MR is the only imaging modality able to visualize bone marrow oedema (BMO), a key predictor of erosive joint damage and functional impairment in adults with RA. Caution is however needed before considering BMO as a prognostic indicator in JIA, since longitudinal studies investigating whether the presence of BMO predates the development of bone erosions are still lacking. Furthermore, signal changes resembling BMO have been recently described in the carpal bones of healthy children. The same was not revealed from similar studies in healthy adults thus highlighting the peculiarities of the growing skeleton and the need to include age-matched healthy subjects in MR studies on JIA.

The availability of normative data is also pivotal for an accurate assessment of bone erosions. Evidence that MR is more sensitive in detecting early erosive damage compare to the others imaging modalities has been provided. However the detection of bony depressions mimicking erosive changes in the carpal bones of healthy children has raised some concern that the higher sensitivity of MR may be to the cost of a reduced specificity [8]. A sound knowledge of growth-related changes is essential prior to use MR to select aggressive phenotype and tailor treatment according to disease severity.

Articular cartilage is a major target of erosive process in JIA. The capability of MR to reliably visualize damage to cartilage in JIA patients has been so far documented only in larger joints. Advancement in imaging technologies has recently allowed to investigate biophysical properties and molecular changes in the composition of cartilage matrix. In particular, T2-relaxation mapping, by providing information on the integrity of type II collagen-based fibrillar network allows to identify very early, and potentially reversible, cartilage molecular abnormalities in JIA.

Musculoskeletal Ultrasound (MSUS)

MSUS has several advantages over other imaging modalities, as it does not entail ionization, allows a safe and multiplane assessment of several joints at one time, and is fairly inexpensive. Joint effusion and synovial hypertrophy are the most common abnormalities detected by grey-scale MSUS. MSUS has proven to be more sensitive than clinical examination in detecting joint inflammation. Since the current ILAR classification is based on the number of affected joints, this issue may be particularly relevant in JIA. The detection of subclinical inflammation by MSUS, in fact, may potentially lead to both reclassifying patients and shifting to a more aggressive treatment [9].

The advent of Doppler modalities has allowed the identification of intra-synovial vascular signals which are of particular benefit in differentiating active synovitis from inactive disease. However, the interpretation of juxta-articular Doppler signal is challenging in children, as it can be a sign of the increased synovial vascularization indicating inflammation, or expression of the physiologically enhanced blood flow of the well-vascularized epiphyseal cartilage of the growing skeleton. Unlike adults, the prognostic meaning of MSUS findings in JIA is still being debated, as abnormalities, including Doppler signal, in children with clinically inactive disease, have been documented not to predict a disease flare [10]. This shortcoming further highlights the need of defining the normal sonographic anatomy throughout paediatric age groups before addressing the role of MSUS in children with JIA.

Tendons are frequently involved throughout JIA course and isolated tenosynovitis may be responsible for joint swelling in children with JIA. The advantage of US over clinical examination in ascertaining whether joint swelling is due to synovitis, tenosynovitis or both, has been largely documented in complex joints with numerous adjacent tendons, such as the ankle or the wrist.

Guidance to local injection therapy represents an important application of MSUS in routine care. US allows the operator to place the needle tip into the joint cavity, tendon sheaths or other peri-articular structures, minimizing the rate of side effects due to delivery of the steroid preparation out of the joint space and maximizing the efficacy of the procedure.

The capability to evaluate joints dynamically and in different spatial planes makes MSUS suitable for capturing bone erosions in sonographically accessible areas. However, the assessment of erosive changes of growing children is challenging as some physiological bone irregularities can be misinterpreted as cortical erosions leading to both an over- or under-estimation of structural damage in children with JIA.

US is well suited for the cartilage assessment in the immature skeleton as it visualizes the cartilage of unossified epiphyses and detects the ossific nuclei several weeks before they become visible by CR. Damage usually appears as cartilage loss with thinning or blurring of its anechoic structure. Recent studies have

documented an acceptable inter- and intra-observer reliability and a good agreement between MSUS and MRI for the measurement of cartilage thickness in several joints; furthermore age- and sex-related normal standards for cartilage thickness for several joints have been established [11].

In childhood, US diagnosis of enthesitis, which is a common feature of the enthesitis-related arthritis (ERA) category of JIA, may be somewhat difficult to make. MSUS evaluation of enthesal inflammation, in fact, requires a thorough knowledge of the age-related anatomic changes as physiological vascularization of the ossification centres next to the entheses can be difficultly discriminated from pathological inflammatory blood flow. In addition the irregular shape of some ossification centres may be misinterpreted as a sign of enthesitis rather than as a normal age-related feature.

Conclusions

Imaging approach to JIA has been radically changing over the last decade and modern imaging modalities such as MR and US are increasingly flanking CR for diagnosis of JIA, assessing its severity, monitoring disease course and treatment efficacy. A thorough knowledge of the relative value of the currently available imaging modalities is necessary to optimize the management of JIA.

MR and US are still in their infancy and further research focusing on the validation and standardization of these techniques is warranted before considering their use in clinical practice. Due to the peculiarities of the growing skeleton, studies aiming to establish normative data for healthy children are of high priority.

IN-DEPTH DISCUSSION II

**Measuring disease activity, physical function and damage
in JIA current clinical practice**

The complexity in the assessment of JIA is mainly related to the absence of a single gold standard measure to support clinical decision making. JIA is a multifaceted disorder and therefore measurement of multiple outcomes, including disease activity, disability and joint damage, is relevant to its management. Most of the currently available outcome measurements are complex, time requiring and have been developed to be used to test assess the effectiveness of antirheumatic drugs in clinical trials or in research setting.

Computational difficulties and data score interpretation further hinder their use in a busy regular clinical setting [1].

A compelling argument is available to suggest that the incorporation of quantitative measures of disease status in standard practice, and adjustments of therapy accordingly (treat-to-target approach), may improve the quality of patient care and disease outcomes on the longer run.

This discussion will focus on the disease assessment indices specifically devised for routine clinical care and on the description of disease status such as inactive disease, minimal disease activity etc., which represent suitable therapeutic targets.

Measures of disease activity

Evaluation of disease activity is a fundamental component of the clinical assessment of children with JIA because persistently active disease is the major determinant of joint damage and physical functional disability. A variety of clinical instruments are available for measuring disease activity, including joint count, global assessment scales, inflammatory serum biomarkers, parent/patient self-reported disease activity. However, due to high disease heterogeneity, no single measure can reliably capture disease activity in all patients. Conversely, evaluation of all measures individually is associated with methodological and statistical problems, especially when these measures are used as clinical endpoints in clinical trials.

Definition of improvement

Measurement of the level of disease activity over time is important to assess the effectiveness of anti-rheumatic drugs in clinical trials and to monitor the patient course in daily care. Response to treatment is currently assessed using validated outcome measures and is calculated as the percentage of change of a core set of clinical variables which consist of; 1) physician global assessment of overall disease activity (PGA); 2) parent/patient global assessment of overall well-being; 3) functional ability; 4) number of joints with active arthritis; 5) number of joints with limited range of motion; 6) erythrocyte sedimentation rate. Using this core set of disease activity measures, response criteria have been created. The American College of Rheumatology paediatric (ACRp) 30 definition of improvement (at least 30% improvement in at least 3 core set variables, with no more than one of the remaining variables deteriorating by more than 30%) has been accepted by

regulatory agencies for drug registration as primary outcome measure in clinical trials in JIA [2]. To provide for more demanding levels of response, ACRp 50, 70, 90 and 100 levels of response have been recently assessed in clinical trials. For ACRp50, ACRp70 or ACRp90, improvement had to be at least 50%, 70% or 90% respectively, with no more than one of the core outcome variables deteriorating by 30% or more. The ACR p response criteria emphasise change in disease state, however, the nature of their calculation does not enable the measurement of actual disease activity and the comparison of one patient's absolute response with that of another. Furthermore, they do not allow discernment of whether one group of patients has more active disease than the other. In this perspective pooling individual measures of disease activity into composite scores appear more effective in order to increase the validity and precision of its evaluation.

Composite scores in JIA

Juvenile Arthritis Disease Activity Score (JADAS) is the first composite disease activity score which aims to quantify the absolute level of disease activity on a continuous scale. JADAS is calculated as the arithmetic sum of the scores of its 4 components: 1) physician global assessment of overall disease activity (PGA), measured on a 0-10 cm visual analogue scale (VAS); 2) parent/patient global assessment of overall well-being, measured on a 0-10 cm VAS; 3) count of joint with active disease assessed in 71 (JADAS-71), 27 (JADAS-27) or 10 (JADAS-10) joints; 4) ESR, normalized to a 0-10 scale (according to the following formula: $[\text{ESR (mm/hour)} - 20]/10$; before making the calculation, ESR values <20 mm/hour were converted to 0 and ESR values >120 mm/hour were converted to 120) [3]. Alternatively, the ESR parameter can be substituted by CRP with High correlation with the original JADAS [1]. Moreover, also the 'clinical JADAS', or cJADAS, which is the JADAS score without CRP or ESR has shown high correlation with the original JADAS scores [1].

The variables included in JADAS are also part of the core set outcome variables included in the ACR Pedi criteria. Restricted joint count and functional assessment were not suited for inclusion in the JADAS because these are affected by disease damage. In validation analysis, JADAS was found to have good metrologic properties, including the ability to predict disease outcome.

JADAS calculation is simple and quick; being a measure with absolute value, it is suitable to determine the disease activity status and course thus increasing the consistency of its assessment across physicians. Moreover, by providing a single number, allows patient/parent to better understand the meaning of disease activity and its course with relevant impact on therapeutic compliance.

Recently JADAS cut-offs values of high and low levels of disease activity have been established, enabling the physicians to have a tighter therapeutic control of disease [4, 5]. Table 1 summarizes these scores for oligo-arthritis and poly-arthritis.

Table 1: cut-offs for disease activity states in oligo and poly-JIA [1].

	JADAS10/71	JADAS27	cJADAS10
Oligoarthritis			
Inactive disease	≤1	≤1	≤1
Low disease activity	1.1 – 2	1.1 – 2	1.1 – 1.5
Moderate disease activity	2.1 – 4.2	2.1 – 4.2	1.51 – 4
High disease activity	>4.2	>4.2	>4
Polyarthritis			
Inactive disease	≤1	≤1	≤1
Low disease activity	1.1 – 3.8	1.1 – 3.8	1.1 – 2.5
Moderate disease activity	3.9 – 10.5	3.9 – 8.5	2.51 – 8.5
High disease activity	>10.5	>8.5	>8.5

Current limitations of JADAS are the Lack of quantification of extra-articular manifestations such as fever and rash (relevant to systemic JIA assessment) and the omission of ocular disease assessment.

Inactive disease, clinical remission and minimal disease activity

Therapeutic advances have increased the expectations of treatment benefits, with disease remission now becoming a realistic goal of any therapeutic intervention in JIA. Preliminary criteria for inactive disease have been established through an international collaborative effort. Accordingly, a patient is classified as having inactive disease at a specific point in time when he/she has no joints with active disease, no systemic manifestations attributable to JIA, no active uveitis, normal values of acute phase reactants, and a PGA indicating no disease activity [6]. Recently, the criteria were modified by adding duration of morning stiffness ≤ 15 minutes. When these criteria are satisfied for at least 6 consecutive months while the patient is receiving anti-rheumatic drugs, the patient is classified as being in state of clinical remission on medication. Disease remission off medication was defined as at least 12 months of inactive disease after discontinuation of all medications [7].

The achievement of complete absence of any signs or symptoms of active disease is however not always possible, particularly among patients with polyarticular or systemic disease. Therefore, a more attainable goal could be to achieve and maintain a state of minimal disease activity which is an intermediate state between high disease activity and remission, though very close to remission. The state of minimal disease activity is defined as the presence of all of the following: PGA of ≤3.5, parent's global rating of well-being of ≤2.5, and swollen joint count of ≤1 in patients with polyarthritis, and PGA of ≤2.5 and swollen joint count of 0 in patients with oligoarthritis. Children with systemic arthritis, RF-positive polyarthritis, RF-negative polyarthritis, or extended oligoarthritis were included in the polyarthritis group. [8]

Evidence has been provided that achievement of disease quiescence helps prevent functional impairment, structural damage and may enhance quality of life and thus is regarded as ideal therapeutic target.

Physical function assessment

The assessment of physical function is a fundamental component of the clinical evaluation of children with JIA. The Childhood Health Assessment Questionnaire (CHAQ) is the most widely used questionnaire on self-estimated functional ability in children with JIA. It assesses functional ability in 8 domains of physical function (dressing, arising, eating, walking, hygiene, reach, grip, activities). The mean score of the eight domains finally makes up the disability index and ranges from 0 (no disability) to 3 (disabled). Utilization of assistance and or aids in a domain sets the score to a minimum of 2 for that domain. The CHAQ is supplemented with two VAS: one for pain, and one for global assessment of overall well-being. The original version has been validated in several languages and different cultures [9]

Although the CHAQ has proved to be valid, reliable, and sensitive to change over time, it is however not routinely incorporated in daily care, due to its complexity, including the requirement of a calculator to compute the score. Studies aiming to set up a functional measure more feasible than CHAQ for routine use in standard clinical care of children with JIA, are therefore warranted.

Assessment of disease damage

So far, in JIA outcome studies, the long-term morbidity has been evaluated in terms of functional disability, as assessed by the C-HAQ. However, despite its widespread use, the C-HAQ may not capture information on several possible forms of damage that may develop in JIA patients over time, such as micrognathia, height retardation, localized growth disturbances, pubertal delay, or visceral organ failure. Permanent changes may also develop in extra articular organs/systems, such as the eye (as a complication of chronic anterior uveitis) or the kidney (due to systemic amyloidosis), or may result from side effects of medications. This morbidity may have a relevant impact on the quality of life of patients and their families

The JADI is intended to rate the extent of damage, defined as persistent changes in anatomy, physiologic status, pathologic processes, or function, that is the result of prior active disease, complications of therapy, or comorbid conditions, that is not due to currently active arthritis, and that is present for at least 6 months despite previous therapies.

The index is composed of 2 parts, one to assess articular damage (JADI-A) and one to address extra-articular damage (JADI-E). In the JADI-A limited ROM, deformity, and previous surgical interventions such as prosthetic replacement, arthrodesis, arthroplasty, or fusion are evaluated in 36 joints and scored in each joint on a 2 point scale (1: partial damage, 2: severe damage, ankylosis, or prosthesis). The maximum total score is 72. The JADI-E explores the presence of damage in 5 different organs/systems. Damage is evaluated using a binary scale (0: absent, 1: present) on 13 items. Due to the relevant impact of ocular damage on the child's health, it

was decided to give a score of 2 for each eye when the patient has had ocular surgery, and a score of 3 when the patient has developed legal blindness. The maximum total score is 17 [10].

Damage is often irreversible and cumulative, and thus, damage scores are most frequently expected to increase or remain stable over time. However, because some forms of damage may improve in paediatric patients, scores may decline in some cases.

The Juvenile Arthritis Damage Index (JADI) is a feasible and easy-to-apply clinical index; it takes only 5–15 minutes for each patient, depending on the amount of damage, making it practical for use in the busy clinical setting. The definitions for scoring each item are concise and simple, in order to make the method accessible even to inexperienced assessors. The JADI represent a promising tool to investigate the full range of factors that can promote long-term morbidity and disability in JIA.

Conclusions

In conclusion a new generation of instruments have been developed in line with current insights about the importance of close monitoring of patients. A tight control strategy, including measurement of disease activity, target setting, and planned adjustment of antirheumatic medication, allows us to improve long term disease outcome and improve the quality of care in patients with chronic inflammatory arthritis.

For applying tight control principle in practice simple tools to quantify multiple outcomes, such as those above illustrated, are relevant for clinicians to know and to apply in daily clinical practice.

EULAR on-line course on Rheumatic Diseases

Miscellaneous inflammatory arthritides:

Adult Still's disease, Sarcoidosis,
Palindromic rheumatism,
Paraneoplastic arthritis,
Hypertrophic osteoarthropathy

Katie Bechman, James Galloway, Jacques Pouchot

A previous version was co-authored by Georg Schett, Jean-Benoit Arlet, Jacques Pouchot, Mart van de Laar, Valentin Schäfer

1. Adult Still's disease

LEARNING OUTCOMES

- Outline the epidemiology of adult Still's disease (ASD)
- Describe associations found in the pathogenesis of ASD in terms of genetics, environmental factors and cytokines
- Describe the clinical manifestations of ASD in terms of fever pattern, and dermatological, musculoskeletal, cardiopulmonary and haematological manifestations
- Describe and evaluate the sensitivity and specificity of laboratory and radiographic findings in ASD
- Describe different sets of classification criteria for ASD, and evaluate their sensitivity and specificity
- Describe the clinical course of ASD in terms of disease patterns and evaluate their prognosis
- Describe treatment options in ASD, and evaluate their level of evidence, efficacy and side effects

1.1 Introduction

Adult onset Still's disease (AOSD) is a rare inflammatory disorder characterised by the classical clinical triad of a daily high spiking fever, arthritis and an evanescent rash. In 1897, Sir George Frederick Still described 22 children with symptoms consistent with the current systemic onset of juvenile idiopathic arthritis (SOJIA) (Still 1990). The first case of an adult exhibiting the same symptoms was reported the year prior in the Lancet (Gerfaud-Valentin, Jamilloux et al. 2014). Following this, numerous cases of patients suffering from high spiking fever, polyarthritis, lymphadenopathy, evanescent rash, sore throat and a striking leucocytosis of unknown origin were described and grouped in Europe under the 'Wissler Fanconi syndrome'. In 1971, Eric Bywaters described the first series of 14 adults with the same symptoms as those seen in paediatric Still's disease, thus defining adult onset Still's disease (Bywaters 1971).

Today the diagnosis AOSD is based on a constellation of symptoms, and Yamaguchi's criteria are one of the most well-known classification criteria (Gerfaud-Valentin, Jamilloux et al. 2014). According to the existing literature, this disease is relatively benign and not usually fatal. However, it can cause macrophage activation syndrome

(MAS) and disseminated intravascular coagulation (DIC), both of which can be life-threatening (Efthimiou, Kadavath et al. 2014, Sakata, Shimizu et al. 2016).

Amongst the group of immune mediated inflammatory disorders managed by rheumatologists, AOSD is often referred to as an 'auto-inflammatory' disorder, signifying the dominant role of the innate immune system in disease pathogenesis, and the notable lack of any associated autoantibodies.

This module will describe in detail the epidemiology, pathogenesis, clinical features, laboratory and radiographic findings, classification criteria, course and treatment options of AOSD.

1.2 Epidemiology

Based on reviews from the 1980s, it appears that AOSD occurs worldwide with estimated annual incidence at 0.16 per 100,000 persons in France, 0.22 in Japan and 0.4 in Norway. (Magadur-Joly, Billaud et al. 1995, Wakai, Ohta et al. 1997, Evensen and Nossent 2006). The disease characteristically affects young adults with equal sex distribution (Efthimiou, Paik et al. 2006, Gerfaud-Valentin, Maucourt-Boulch et al. 2014), although Japanese and Chinese studies report a slight female dominance. (Sakata, Shimizu et al. 2016). A retrospective observational study of 62 patients from France demonstrates a bimodal peak at disease onset at ages 15-25 years and 36-46 years (Magadur-Joly, Billaud et al. 1995). A Dutch retrospective review of 45 patients demonstrated the median age of onset at 25 years (range 16–65), with 27% of the patients showing the first symptom after the age of 35 (Wouters and van de Putte 1986). Interestingly, a large retrospective study of 513 patients from Japan demonstrated a later onset of disease with about half of the patients greater than 55 years old and approximately 16 % were ≥ 75 years old (Sakata, Shimizu et al. 2016). This may be explained by an aging population and regional differences in presentation across ethnicities.

When onset of AOSD occurs before 16 years old, the disease is called Systemic onset Juvenile Idiopathic Arthritis (SoJIA). Whether AOSD and SOJIA are the same disease remains controversial. SOJIA is considered a subtype of juvenile idiopathic arthritis (JIA), however evidence suggests it should be considered apart from JIA because of clear differences in epidemiology, clinical manifestations, pathophysiology and response to treatment. It is more likely to belong to the auto inflammatory diseases along the same continuum as AOSD.

1.3 Pathogenesis

1.3.1 Genetics

Although no familial trend has been reported, some studies have reported some associations with HLA antigens. HLA-Bw35 was the first identified as a susceptibility antigen and associated with a mild self-limited pattern of disease (Terkeltaub, Esdaile et al. 1981). HLA DR4 was found more prevalent in 29 AOSD cases versus healthy controls and HLA DRw6 was associated with the occurrence of proximal arthralgia (Wouters, Reekers et al. 1986). In a retrospective review on 55 patients from Canada, a strong association was seen with HLA-B17, -B18,

-B35 and -DR2, however other studies failed to confirm these findings (Pouchot, Sampalis et al. 1991). The lack of consistent results may reflect an absence of associated or wide heterogeneity of such associations between different ethnic groups (Gerfaud-Valentin, Jamilloux et al. 2014).

Interestingly, no mutation in genes involved in hereditary autoinflammatory disease has been associated with AOSD. Polymorphisms have been described in genes encoding innate immunity-associated factors and cytokines, and include IL-6, IL-1a, IL1-RN, Macrophage inhibitory factors (MIF) in patients with SOJIA and IL-18 or MIF in patients with AOSD. These polymorphisms are anecdotal and likely to have very low penetrance suggesting that a polygenic pattern of inheritance is likely (Gerfaud-Valentin, Jamilloux et al. 2014, Jamilloux, Gerfaud-Valentin et al. 2015).

1.3.2 Environmental factors

A number of epidemiological aspects of AOSD support the hypothesis that the disease is triggered by an environmental source, including clinical features (frequent onset of pharyngitis in prodrome) and seasonality. As in SoJIA, a number of viruses and bacterial have been isolated in AOSD patients (Jamilloux, Gerfaud-Valentin et al. 2015) (table 1). The observation that many different infectious agents may act as disease triggers, suggests a similarity with reactive arthritis. Overall, AOSD does not seem to be an infectious disease but rather an autoinflammatory disease in which infections or environmental agents may trigger a flare up.

Table 1: Viruses and bacteria isolated in AOSD patient (Efthimiou, Paik et al. 2006).

Viruses	Bacteria
Rubella and Mumps, Echovirus 7, Cytomegalovirus, Epstein-Barr virus, Parainfluenza, Coxsackievirus B4, Adenovirus, Influenza A, Human herpes virus 6, Parvovirus B19, Hepatitis B and C	<i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , <i>Yersinia enterocolitica</i> 3 and 9, <i>Brucella abortus</i> , <i>Borrelia burgdoferi</i>

1.3.3 Immunopathogenesis

Immune dysregulation including cytokine mediated inflammation and dysregulated apoptosis is implicated in the development of AOSD (Kadavath and Efthimiou 2015). A hallmark of the condition is activation of the innate immune pathway with prominent neutrophil and macrophage involvement.

A proposed pathophysiological model suggests that environmental triggers, termed danger signals, activate a dysregulated NLRP3 inflammasome, which in turn triggers the activation and secretion of pro-inflammatory cytokines (IL-1 β and IL-18) and Th1 polarisation of CD4 T cells. At the same time, these danger signals activate toll-like receptors 7 which cause dendritic cells to induce Th17 response. Th17 cells secrete IL-17 which stimulates the production of chemokines and neutrophil recruitment (Gerfaud-Valentin, Jamilloux et al. 2014, Jamilloux, Gerfaud-Valentin et al. 2015).

IL-1 β can induce its own production through IL-1 receptor in an autocrine process. IL-18 is also processed through the inflammasome machinery. It induces production of Th1 cytokines. It also triggers a natural killer (NK) cell mediated IFN γ production, which in turn increases macrophage activation. These NK cells are abnormal with decreased cytotoxic function. Serum concentrations of IL-1 β and IL-18 are significantly higher in AOSD patients than in controls (Gerfaud-Valentin, Jamilloux et al. 2014, Jamilloux, Gerfaud-Valentin et al. 2015).

Downstream of IL-1 β several other cytokines have important roles including IL-6, TNF α and IL-8. IL-6 is responsible for some of the clinical features (fever, rash) and the liver synthesis and fast release of ferritin. Its levels are correlated with disease activity. Additionally, many chemokines are involved in the inflammatory reaction including CXCL8, a major neutrophil inducer and CXCL1 (Gerfaud-Valentin, Jamilloux et al. 2014, Jamilloux, Gerfaud-Valentin et al. 2015).

1.4 Clinical manifestations

1.4.1 Fever

This is often the initial symptom preceding other manifestations. The fever is usually of sudden onset and generally exceeds 39°C. It is transient and is most commonly quotidian or double quotidian in pattern, with the highest temperatures seen in the late afternoon or early evening (Larson 1985) (figure 1). It is present in almost all patients. (Pouchot, Sampalis et al. 1991, Efthimiou, Paik et al. 2006, Gerfaud-Valentin, Jamilloux et al. 2014).

Figure 1 Body temperature curve in adult Still's disease. (Source: CRI (Club Rhumatismes et Inflammation) <http://www.cri-net.com>)

1.4.2 Rash

The typical skin rash is classically described as evanescent, salmon-pink, macular or maculopapular erythema (figure 2). It appears or becomes more prominent with the onset of fever. It is found predominantly on the trunk and proximal extremities (Kadavath and Efthimiou 2015). It can be mildly pruritic and associated with a burning sensation. A Koebner's phenomenon has been described (Pouchot, Sampalis et al. 1991) Histology shows perivascular inflammation of the superficial dermis with invasion of lymphocytes and histiocytes, and immunohistochemistry is sometimes positive for complement and immunoglobulin (Pouchot, Sampalis et al. 1991, Efthimiou, Paik et al. 2006). Overall, the incidence of the rash in AOSD is from 51% to 87% (Efthimiou, Paik et al. 2006)

Figure 2 Transient, salmon-pink, maculopapular erythema, on the trunk. (Source: CRI (Club Rhumatismes et Inflammation), <http://www.cri-net.com>)

1.4.3 Sore throat

Sore throat is an early manifestation in approximately 70% of cases AOSD and can precede fevers and other symptoms. It is also commonly observed during occurrence of subsequent disease flares. It has been linked to a viral infection, although imaging studies have suggested inflammation of the crico-arythenoid joints, plus perichondritis of cricothyroid cartilage that may be the cause of symptoms (Nguyen and Weisman 1997, Chen, Lan et al. 2007).

1.4.4 Musculoskeletal disease

Arthralgia and arthritis are found in the majority of patients with AOSD, with incidences ranging from 64% to 100% (Efthimiou, Paik et al. 2006). Joint involvement is typically oligoarticular with pain associated with fever spikes. Symptoms are transient, resolving as the fever diminishes (Efthimiou, Paik et al. 2006). However, joint disease can evolve over months into a more destructive form. The joints affected most frequently are the knees, wrists and ankles, although involvement of the elbows, shoulders, proximal and distal interphalangeal joints,

metacarpophalangeal and metatarsophalangeal joints, temporomandibular joints, and hips have been described as well (Bywaters 1971, Elkon, Hughes et al. 1982, Pouchot, Sampalis et al. 1991, Masson, Le Loet et al. 1995). Of note, AOSD arthritis has a predilection for the carpal and pericarpitate bones. Changes in the wrist typically present 6 months after disease onset, with progressive joint space narrowing, with ankylosis developing after 1.5–3 years (Medsger and Christy 1976).

Generalised myalgia is common, with an incidence of 56-84%. Myalgia may coincide with the fever spike. It may be severe and debilitating, but an inflammatory myopathy is rarely found (Efthimiou, Paik et al. 2006) (Masson, Le Loet et al. 1995).

1.4.5 Liver disease

Hepatomegaly and modest liver biochemistry abnormalities occur in 50-75% of patients. Acute hepatitis or hepatic failure is extremely rare, and most of the reported cases occurred during treatment with hepatotoxic drugs or in the setting of macrophage activation syndrome (Reginato, Schumacher et al. 1987) (Mylona, Golfinopoulou et al. 2008).

1.4.6 Lymphadenopathy and splenomegaly

Tender cervical lymphadenopathy and splenomegaly occur in 50% of patients. Lymph node biopsy findings may resemble lymphoma on light microscopy, but immunohistochemistry demonstrates benign polyclonal B cell hyperplasia (Quaini, Manganelli et al. 1991).

1.4.7 Cardiopulmonary disease

Cardiopulmonary manifestations include pleuritis, pericarditis and transient pulmonary infiltrates occurring in 30-40%. These improve rapidly after treatment (Gerfaud-Valentin, Jamilloux et al. 2014). Pericarditis is mild in nature but in rare cases has been reported to lead to tamponade (Reginato, Schumacher et al. 1987). Rarely, pulmonary disease may become severe, progressing to ARDS. Chronic interstitial lung disease and pulmonary hypertension are rare (Campos and Schiopu 2012) (Cheema and Quismorio 1999).

1.4.8 Haematological manifestations

Macrophage activation syndrome (MAS) or reactive haemophagocytic syndrome (RHS) is a life threatening complication of AOSD with a reported mortality between 10-22% (Efthimiou, Kadavath et al. 2014). Despite a very rare condition, MAS in AOSD has likely been underdiagnosed and is in fact more common than previously recognized (Arlet, Le et al. 2006).

Clinical and biological features of MAS closely resemble reactive haemophagocytic lymphohistiocytosis (HLH) and the disease is in fact considered as secondary subclass of HLH (Davi, Consolaro et al. 2011). MAS is characterised by an uncontrollable activation and non-malignant proliferation of T lymphocytes and

macrophages which lead to phagocytosis of haematopoietic cells in various organs. The underlying physiopathology is not well understood. There is impairment of cytotoxic function with a reduced number or defective activity of CD8⁺ lymphocytes and NK cells. The perceived failure of complete pathogen destruction results in persistent lymphocyte and macrophage activation. Macrophage activation subsequently results in tissue infiltration, production of ferritin and high levels of cytokines (TNF α and IL-6, IL-18, IL-8) (Grom 2003).

MAS most commonly occurs early on during the course of AOSD (Lenert and Yao 2016). MAS and AOSD share several clinical and laboratory features which may explain the difficulty in recognizing the condition when it complicates a flare of AOSD. Some red flag clinical features including renal insufficiency, lung involvement with hypoxia, hypotension, and DIC, should raise concern for the impending development of MAS (Lenert and Yao 2016). Laboratory findings include pancytopenia with lymphopenia in particular and high serum levels of ferritin, triglycerides, and liver enzymes, whilst paradoxically demonstrating a normal erythrocyte sedimentation rate, due to increased fibrinogen consumption (Sawhney, Woo et al. 2001, Lenert and Yao 2016). It is important to acknowledge that hyperferritinaemia is a classical laboratory finding in AOSD even without overt MAS, but extreme ferritin elevation (>10,000 ng/mL) in the context of cytopenias should prompt urgent evaluation for MAS.

Gold standard diagnostic criteria for MAS in AOSD are lacking. The presence of haemophagocytosis on bone marrow examination has been regarded as a standard criterion for diagnosis. However, this finding may be absent in up to 40% of patients. The HLH 2004 criteria have been traditionally used for identifying MAS in patients with autoimmune diseases (Kumakura, Ishikura et al. 2004, Henter, Horne et al. 2007) (Box 1). The Ravelli criteria have been refined to increase post-test probability for earlier identification of MAS in SOJIA (Ravelli, Magni-Manzoni et al. 2005) (Box 2). As MAS is becoming better studied and defined, novel associations and tests are being used. Soluble IL-2 receptor α (sCD25), reflective of T cell activation, and soluble CD163, related to activation of phagocytic macrophages/histiocytes, might be useful as diagnostic markers of MAS and helpful in monitoring disease activity and response to treatment.

Box 1. Haemophagocytic lymphohistiocytosis (HLH) criteria 2004 (Henter, Horne et al. 2007)

The diagnosis *non-familial HLH* is established with the presence of five criteria or more

- fever
- splenomegaly,
- peripheral blood cytopenias affecting at least 2 of 3 cell lineages
- hypertriglyceridemia or hypofibrinogenaemia
- microscopic evidence of haemophagocytosis in the bone marrow, spleen, or lymph nodes,
- low or absent natural killer (NK) cell activity,
- elevated ferritin levels
- elevated soluble CD25 (sCD25; IL-2 receptor) levels

Adapted from (Henter, Horne et al. 2007)

Box 2 Preliminary guidelines for MAS complicating SoJIA (Ravelli, Magni-Manzoni et al. 2005)*Presence of ≥ 2 laboratory criteria or ≥ 2 clinical and/or laboratory criteria***- Laboratory criteria include**

- platelet count $\leq 262 \times 10^9/\text{litre}$,
- aspartate aminotransferase level > 59 units/litre
- white blood cell count $\leq 4.0 \times 10^9/\text{liter}$ ~~litre~~ blood cell count $\leq 4.0 \times 10^9/\text{litre}$

- Clinical criteria include

- hepatomegaly,
- haemorrhagic manifestations,
- central nervous system (CNS) dysfunction

- Demonstration of macrophage haemophagocytosis on bone marrow aspirate only in doubtful cases.*Adapted from Ravelli, Magni-Manzoni et al. 2005*

Other haematological complications in AOSD are rare. Pure red cell aplasia, thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome have been described. (Bagnari, Colina et al. 2010)

1.5 Laboratory and radiographic findings

1.5.1 Laboratory findings

The laboratory findings in AOSD reflect the systemic inflammation and cytokine cascade present, and none of the findings are specific for AOSD. This is no association with antinuclear antibodies or rheumatoid factors. Erythrocyte sedimentation rate and C-reactive protein are raised in virtually all patients.

1.5.1.1 Haematological studies

Neutrophilic leukocytosis remains as the most common haematological abnormality (98%) and may allow differentiation from other fevers of 'unknown origin'. Most patients have a normocytic, normochromic anaemia (anaemia of chronic disease) especially during active disease, and a reactive thrombocytosis is common. (Efthimiou, Paik et al. 2006, Gerfaud-Valentin, Jamilloux et al. 2014). Disseminated intravascular coagulation may occur.

1.5.1.2 Liver function studies

Liver abnormalities are common with raised serum aminotransferase, lactate dehydrogenase, γ -glutamyltransferase and bilirubin are seen in 75% of patient with AOSD. The pathophysiology of liver involvement is not known; cytokine production and sustained macrophage activation are implicated. Liver biopsy findings are non-specific (Pouchot, Sampalis et al. 1991, Efthimiou, Kadavath et al. 2014) (Kong, Xu et al. 2010).

1.5.1.3 Serum ferritin

AOSD is associated with marked increase in ferritinaemia, higher than seen in other inflammatory disease. Ferritin is an acute phase reactant, produced by the histiocytic / macrophage systems under the influence of IL-1 β , IL-18, TNF α and also released by damage hepatocytes. There is increasing evidence that ferritin not only reflects the acute phase response but may play critical pro-inflammatory functions.

It has been suggested that rare conditions such as AOSD, reactive HLH and catastrophic anti-phospholipid syndrome should be group together due to their exceptionally high serum ferritin levels and subsequent cytokine storms by the term 'hyperferritinaemic syndrome' (Narula, Narula et al. 2015). Extreme ferritin elevations have also been reported in other settings such as HIV seroconversion (Babiker, Wingfield et al. 2015).

A Chinese series found 99% of patients with AOSD had elevated ferritin levels with 51% having levels of 1000–1500 ng/ml, and 32% having more than 1500 ng/ml (Kong, Xu et al. 2010). Levels ranging between 4000 ng/ml and 30,000 ng/ml are not infrequent, although levels >10,000 ng/ml are often associated with MAS (Arlet, Le et al. 2006). A threshold five times the normal value (ie 1000-1500 ng/ml) is suggestive of AOSD (Ota, Higashi et al. 1987). However the specificity remains poor as similar levels may be seen during infection, neoplastic conditions, haemochromatosis or storage disease such as Gaucher. Serum levels seem to correlate with disease activity, normalising when the disease goes into remission.

1.5.1.4 Glycosylated ferritin

A more specific marker may be to consider with the drop in glycosylated ferritin, as an isoform of ferritin. In healthy subjects 50-80% of ferritin is observed in its glycosylated isoform. In inflammatory disease this level drops to 20-50%, and in AOSD it is noted at less than 20%. It remains low in both the active phase of the disease and in remission (Fautrel, Le Moel et al. 2001).

1.5.2 Radiographic findings

No radiographic findings are specific for AOSD and changes vary from normal to soft-tissue swelling, joint effusion, or mild periarticular demineralisation. A classical pattern is non erosive intercarpal and carpometacarpal joint space narrowing of the wrist reported in 41%, which was bilateral in 69%, presenting 6 months after disease onset and developing to ankyloses in 25% in 3 years (Pouchot, Sampalis et al. 1991) (Medsger and Christy 1976) (Figure 3 and 4). Ankylosis of other joints is less common. An unusual complication of AOSD is the rapid destruction of the hip and, less commonly, the knee, which can require total joint arthroplasty (Cabane, Michon et al. 1990).

Figure 3 Isolated carpal disease with fusion in the course of adult Still's disease. (Source: CRI (Club Rhumatismes et Inflammation), <http://www.cri-net.com>)

Figure 4 Isolated carpal disease with fusion in the course of adult Still's disease.

1.6 Classification criteria

There are no specific diagnostic tests for AOSD and the diagnosis is made upon the presence of characteristic clinical and laboratory features in the absence of another condition that may cause similar findings; infections, neoplasm and other autoimmune diseases. Several classification criteria have been proposed. The Yamaguchi's criteria are the most widely cited and provide the highest sensitivity (93%) (Yamaguchi, Ohta et al. 1992), although within these criteria the exclusion of other diseases is required (Box 3). In 2002, Fautrel et al. proposed a new set of criteria which contained serum ferritin and glycosylated ferritin and did not contain exclusion criteria (Box 4). The sensitivity and specificity of Fautrel criteria were 80.6% and 98.5%, respectively (Fautrel, Zing et al. 2002). This classification criteria has been recently validated in a cohort independent of that used for the original publication (Lebrun, Mestrallet et al. 2017).

Box 3. Yamaguchi criteria

The diagnosis ASD is established with the presence of five criteria or more, with at least two major criteria present and no exclusion criteria (96% sensitivity; 92% specificity) (Yamaguchi et al, 1992).

Major criteria

- Fever of at least 39°C, intermittent, lasting ≥ 1 week
- Arthralgias or arthritis, lasting ≥ 2 weeks
- Typical rash
- Leucocytosis ($\geq 10\,000/\mu\text{L}$), with $\geq 80\%$ granulocytes

Minor criteria

- Sore throat
- Recent development of significant lymphadenopathy
- Hepatomegaly or splenomegaly
- Abnormal liver function studies, particularly aminotransferases and lactate dehydrogenase
- Negative tests for antinuclear antibody and rheumatoid factor

Exclusion criteria

- Infections
- Malignancies
- Other rheumatic diseases

Adapted from Yamaguchi et al, J Rheumatol 1992;19:424–30.

Box 4. Fautrel criteria

Four major criteria or three major and two minor criteria.

Major criteria

- Spiking fever ($\geq 39^\circ\text{C}$)
- Arthralgias
- Transient erythematous rash
- Sore throat
- Polymorphonuclear cells $\geq 80\%$
- Glycosylated ferritin $\leq 20\%$

Minor criteria

- Maculopapular rash
- Leucocytosis ($\geq 10\,000/\mu\text{L}$)

1.7 Course

1.7.1 Monophasic, polycyclic systemic and chronic articular

The outcome of AOSD is unpredictable and the disease is conventionally divided into three different subtypes based on disease evolution; 1) self-limited or monophasic, 2) intermittent or polycyclic systemic; and 3) chronic articular. Both monocyclic and polycyclic patterns are more common than the chronic articular pattern (Wouters and van de Putte 1986). The self-limited monophasic pattern is characterized by a single disease episode with systemic symptoms typically involving fever, rash, serositis, and organomegaly. Remission is achieved in most within 1 year, with a median duration of 9 months. The polycyclic systemic pattern is characterised by recurrent disease flares interspersed with complete remissions which can last from 2 weeks to 2 years. Subsequent flares tend to be shorter and less severe and may be years apart (Pouchot, Sampalis et al. 1991, Kadavath and Efthimiou 2015). The chronic articular pattern is characterised by persistent active disease, predominantly articular manifestations with joint destruction, which can mimic other chronic inflammatory arthritides. Involvement of shoulder and hip at disease onset with cutaneous involvement is associated with a worse prognosis than those with only systemic involvement (Pouchot, Sampalis et al. 1991, Kadavath and Efthimiou 2015).

1.7.2 Dichotomous view on clinical expressions and cytokine profile

A new conception of AOSD divided into two distinctive phenotypes is currently emerging based on clinical observations and on studies investigating cytokine profiles and responses to specific biologic treatments. These two subtypes are distinguished according to the dominant clinical expression; those patients that exhibit primarily systemic symptoms with multi-organ involvement, increased levels of inflammatory markers and ferritin and the risk of MAS, more in keeping with an autoinflammatory group of disorders; and those patients that exhibit chronic polyarthritis and a lower inflammatory state in keeping with a seronegative rheumatic disease (Maria, Le Quellec et al. 2014). Some patients may present with systemic flares at the onset of their disease but progressively evolve into a chronic erosive polyarthritis.

1.8 Treatment

Evidence for treatment in AOSD remains largely empirical, derived from single case reports, small case series or retrospective cohort studies. The rarity of AOSD makes it difficult to carry out controlled clinical trials and none has been conducted in adults (Pouchot and Arlet 2012).

1.8.1 Nonsteroidal anti-inflammatory drugs and corticosteroids

Historically, patients with AOSD have been treated along similar regimen as children having the SoJIA with high-dose aspirin or other NSAIDs. However more than 80% of AOSD patients did not achieve remission with this treatment and in the majority corticosteroids are necessary. Nevertheless, temporary use of NSAIDs can be considered during diagnostic workup or for early relapse of the disease (Franchini, Dagna et al. 2010, Jamilloux, Gerfaud-Valentin et al. 2015). Often high therapeutic levels of salicylates are required (Pouchot and Arlet 2012).

Corticosteroids remain the first-line treatment for AOSD regardless of clinical presentation. The usual dose is 0.5-1 mg/kg/day, and pulses of methylprednisolone have been used for severe disease refractory to oral corticosteroids. There are however conflicting reports regarding the impact of the dose or route of administration on therapeutic response (Kong, Xu et al. 2010, Gerfaud-Valentin, Maucourt-Boulch et al. 2014). Several case series report greater efficacy of corticosteroids in those with systemic symptoms compared to those with articular disease. In a series of 45 patients, prednisone monotherapy achieved satisfactory control of disease in more than 79% of the trials administered to those with systemic symptoms, but only 35% of the trials in the articular disease group. Furthermore, 80% of patients whose arthritis did not respond to prednisone within the first 3 months would proceed on a chronic disease course, compared with only 18% of the corticosteroids responders.(Franchini, Dagna et al. 2010). Corticosteroids dependence in AOSD is high, reported at 45%, more prevalent in the polycyclic and chronic forms (Gerfaud-Valentin, Maucourt-Boulch et al. 2014).

1.8.2 Disease modifying anti Rheumatic drugs

In case of corticosteroid failure or dependence, immunosuppressive drugs can be used. Methotrexate remains the first-line corticosteroid-sparing drug in AOSD, although benefits have been reported with cyclosporine A (Mitamura, Tada et al. 2009), azathioprine, leflunomide, hydroxychloroquine (Franchini, Dagna et al. 2010), and tacrolimus (Nakamura, Odani et al. 2014).

1.8.2.1 Methotrexate

In a retrospective cohort of 26 patients with AOSD, 23 (88%) responded to low dose methotrexate (mean dose 11.5 mg/week) with 18/23 (78%) achieving complete remission and 11/26 (42%) able to discontinue their corticosteroids (Fautrel, Borget et al. 1999). Methotrexate seems especially effective for the treatment of polyarthritis. Methotrexate induced hepatotoxicity does not seem to occur more frequently in AOSD than in adult rheumatoid arthritis.

1.8.2.2 Intravenous immunoglobulin IVIG

Data concerning on IVIg in AOSD is more controversial. In 2 open-label studies, IVIg was shown to be effective early in the disease course but other studies have found this treatment had no consequence on the course or the prognosis of AOSD (Permal, Wechsler et al. 1995, Vignes, Wechsler et al. 1998). It is however well tolerated and may be useful in life-threatening situations or in cases of AOSD flare-up during pregnancy.

1.8.3 Targeted biologic therapies

Although dramatic responses have been reported in SoJIA when given as first-line treatment, targeted biologic agents are actually reserved for refractory AOSD. Resistance to corticosteroids and DMARDs defines refractory AOSD, which mostly includes the polycyclic or chronic patterns of the disease. Anti-IL1 is generally used as the first line biologic and anti-IL6 is generally considered the second line biologic, although may be used first line in severe disease, especially in light of the efficacy data in systemic onset JIA that have emerged (De Benedetti, Brunner et al. 2012). Anti-TNF was historically the first line biologic, although is now reserved when other options fail.

1.8.3.1 IL-1 antagonists

Three IL-1 antagonists are presently available, a recombinant antagonist of the IL-1 receptor (IL-1Ra, anakinra), a human monoclonal antibody directed against IL-1 β (canakinumab), and a soluble IL-1 trap fusion protein (rilonacept). Anakinra has been more frequently reported in the treatment of AOSD. The rationale of IL-1 inhibition in AOSD lies in the demonstration of elevated IL-1 levels in active untreated disease and empirical evidence from the successful treatment of the auto-inflammatory syndromes with IL-1 inhibition (Kontzias and Efthimiou 2012). Compiled data from a recent comprehensive literature review on each anti-IL-1 agent, reported similar rates of full or partial remission. Primary treatment failures were rare, but efficacy was lost over time in some cases (Junge, Mason et al. 2017).

1.8.3.1.1 Anakinra

Despite the lack of randomised controlled trials in AOSD, anakinra seems to have an impressive rapid and sustained efficacy, associated with a corticosteroid-sparing effect in most patients (Pouchot and Arlet 2012). Its effect seems to be greater in patients with highly active systemic disease than in patients with isolated chronic arthritis (Jamilloux, Gerfaud-Valentin et al. 2015). The first use of anakinra was an open-label study on 4 patients with disease refractory to methotrexate, of which 2 had disease refractory to etanercept. Treatment resulted in a rapid and complete resolution of both systemic and articular manifestations, sustained during a 6–14 month follow-up period (Fitzgerald, Leclercq et al. 2005). Single case reports have reiterated this remarkable effect, sometimes in those with life-threatening manifestations (Vasques Godinho, Parreira Santos et al. 2005, Debiais, Maillot et al. 2008) and benefit was reported in 1 prospective, randomized, open-label trial (Nordstrom, Knight

et al. 2012). Lequerré et al in a retrospective survey of anakinra therapy in 35 patients (20 with SoJIA and 15 with AOSD) demonstrated similar results. All 15 patients with AOSD had disease refractory to methotrexate, and 10 had also failed anti-TNF α therapy. A total of 11 AOSD patients achieved rapid and major improvement with at least a 50% improvement for all disease markers (Lequerre, Quartier et al. 2008). The largest retrospective observational study evaluated the efficacy and safety of Anakinra in 140 AOSD patients. Treatment was effective in improving all clinical and serological manifestations, with a good response noted at 3 months after therapy onset. Skin reaction were the main causes for discontinuation (Colafrancesco, Priori et al. 2017). Other data regarding anakinra efficacy is available from studies in SoJIA (Swart, Barug et al. 2010). Nigrovic et al. observed rapid resolution of systemic symptoms in more than 95% of cases with an additional preventive effect on refractory arthritis in almost 90% with anakinra as s first-line treatment. Nigrovic postulated that there could be a “window of opportunity” for IL-1 blockade very early in the course of the disease in SoJIA (Nigrovic, Mannion et al. 2011).

Anakinra is given as 100mg subcutaneously daily, due to its short half-life of 4–6 hours. Injection site reactions have been reported. Other side effects are uncommon (Lequerre, Quartier et al. 2008, Pouchot and Arlet 2012).

1.8.3.1.2 Canakinumab

Canakinumab has a longer half-life of 26 days, and thus is administered every 8 weeks. It was reported to be successful in two case of AOSD who were resistant to short-acting IL-1 blockade with anakinra (Kontzias and Efthimiou 2012). However, the high cost of this drug currently precludes widespread use in most healthcare settings.

1.8.3.1.3 Rilonacept

Rilonacept is a soluble dimeric fusion protein that binds to both IL-1 β and IL-1 α and prevents its interaction with cell surface receptors. It is also longer-acting with a half-life of 8.6 days, administered as a weekly subcutaneous injection (220 mg loading dose and 160 mg maintenance dose). Small cohort and case series have reported successful use in patients with refractory AOSD (Petryna, Cush et al. 2012). One study reported high levels of IL-18 at baseline as a predictor of a successful response (Henderson and 10.1002/art.29596 2010;)

1.8.3.2 Inhibitors of IL-6

IL-6 is another pro-inflammatory cytokine through to play an important role in the pathogenesis of AOSD. Serum levels of IL-6 are commonly markedly elevated in active disease and as such it is considered as a suitable target for the treatment.

1.8.3.2.1 Tocilizumab

Tocilizumab is a humanised anti-IL-6 receptor antibody that recognises both the membrane-bound and the soluble form of IL-6 receptor, blocking the actions of IL-6. Tocilizumab is used less widely in treating AOSD and should be used only if anti-IL-1 treatments fail to control the disease or if relapses occur during weaning of anti-IL-1 (Jamilloux, Gerfaud-Valentin et al. 2015). The safety profile seems identical to that reported in rheumatoid arthritis (Pouchot and Arlet 2012).

A small case series on three patients with AOSD who were refractory to standard treatment and cytokine blockade with anakinra and TNF α blockers demonstrated complete remission with tocilizumab therapy (Rech, Ronneberger et al. 2011). A Japanese survey reported a favourable response in both systemic and articular symptoms in 11 patients treated with tocilizumab after failure with TNF α blocker or anakinra. The tocilizumab treatment group had the highest continuation rate, with a tendency for large corticosteroids-sparing effects (Suematsu, Ohta et al. 2012).

In a French review of 14 patients with refractory AOSD treated with tocilizumab, at 6 months a EULAR remission (DAS < 2.6) was achieved in 57% of the patients, and resolution of systemic manifestations was observed in 86%. In most patients, response to tocilizumab was rapid and sustained (Puechal, DeBandt et al. 2011). A recent systematic review identified 35 patients with AOSD treated with tocilizumab for AOSD of which 94% had unsuccessfully tried other immunosuppressive agents including TNF α blocker and anakinra. They reported a prompt articular improvement in 86% and disappearance of systemic symptoms in 96% (de Boysson, Fevrier et al. 2013). Similar findings were reported in a retrospective open label study rapid although joint manifestations appeared more refractory to treatment compared with systemic manifestations. (Ortiz-Sanjuan, Blanco et al. 2014)

1.8.3.3 Anti-Tumour Necrosis Factor α

Historically anti-TNF α drugs were the first biologics used to treat refractory AOSD with supporting data from case reports, retrospective case series, and one open-label trial. TNF α inhibitors were used along the same regimen as adopted for treatment of rheumatoid arthritis. Results were retrospective and rather heterogeneous, although responses appeared more favourable in the setting of chronic polyarticular disease (Gerfaud-Valentin, Maucourt-Boulch et al. 2014).

1.8.3.3.1 Infliximab

Infliximab was the first TNF α blocker to be used in AOSD. In a small case series of six patients there was a rapid and sustained effect in both systemic and articular manifestations (Kraetsch, Antoni et al. 2001). In two other small case series with seven patients with disease resistant to MTX, the addition of infliximab was effective in

all but one patient (Cavagna, Caporali et al. 2001, Kokkinos, Iliopoulos et al. 2004). However, less effective results were noted in a retrospective study conducted by the French 'Club Rhumatismes et Inflammation' group on all prescriptions of anti-TNF α (infliximab and etanercept) in twenty patients with chronic AOSD resistant to conventional DMARDs. A complete response (complete resolution of all clinical and laboratory features) was seen in 4 out of 15 (27%) and a partial response (persistence of one or several AOSD related manifestations) in 9 out of 15 (60%). Ten out of the 15 patients treated with infliximab discontinued treatment after a mean duration of 9 months due to lack of efficacy or side effects (Fautrel, Sibilia et al. 2005). Side effects reported included infusion reactions, cutaneous eruptions, recurrent bronchitis and pneumonia, pneumonitis, heart failure, visual disturbance and fulminant hepatitis in a patient with concomitant hepatitis B (Efthimiou, Paik et al. 2006).

1.8.3.3.2 Etanercept

Etanercept was used in a prospective open-label study in 12 AOSD patients with chronic polyarthritis resistant to conventional therapy. At 6 months, 7 of 12 patients achieved an ACR-20, of which 4 achieved ACR-50 and 2 an ACR-70. Three patients had concomitant systemic manifestations and only one of them improved (Husni, Maier et al. 2002). Other positive case reports have been published, but it is important to acknowledge the inherent publication bias that arises in the case report literature. A further retrospective study again from the French 'Club Rhumatismes et Inflammation' group, reported that out of 10 patients treated with etanercept, only one achieved a complete response and seven a partial response (Fautrel, Sibilia et al. 2005). Side effects associated with etanercept use in AOSD include injections site reactions, paradoxical disease flares, cutaneous eruptions, infection complications and diarrhoea (Efthimiou, Paik et al. 2006).

1.8.3.3.3 Adalimumab

Adalimumab has been used and was effective in fewer than 10 patients (Pouchot and Arlet 2012).

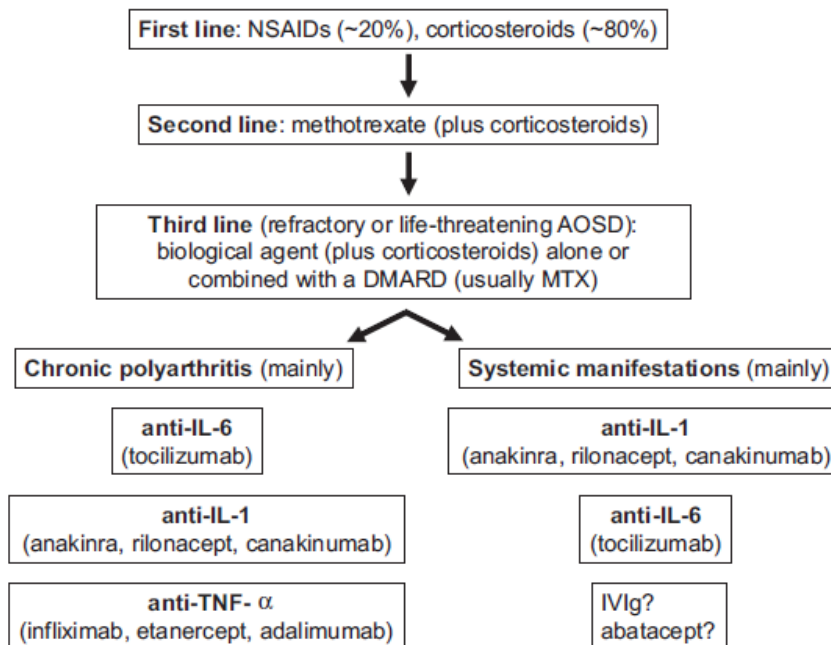

1.8.3.4 Other biological agents

Emerging data on other cytokine pathway blockers continues to emerge. This include recent positive phase 2 trial results of il-18 inhibition in patients with refractory AOSD (Gabay, Fautrel et al. 2017). Abatacept been used in four patients with AOSD and was reported to be effective in two. Rituximab has been tried in four patients but was not effective (Pouchot and Arlet 2012).

1.8.3.5 Therapeutic Strategies

A therapeutic strategy in management is outlined below (figure 5)

Figure 5. Therapeutic strategies in adult-onset Still's disease (AOSD) (adapted by Pouchot et al, best Practice & research Clinical Rheumatology)

Legends: IL: interleukin; IVIg: intravenous immunoglobulins; TNF: tumour necrosis factor

1.8.4 Management Macrophage activation syndrome

Empiric treatment of MAS traditionally consisted of the following agents alone or in combination: intravenous pulse corticosteroids, immune gamma globulin (IVIg), and cyclosporine A (CyA). Corticosteroids therapy has a well-established key role. Cyclosporine was found to be dramatically efficacious in patients whose disease was refractory to high-dose intravenous corticosteroids in the mid-1990s. It is also used in treating HLH (Ravelli, De Benedetti et al. 1996).

There are several reports of the use of IL-1 inhibitors in the management of MAS in SoJIA (Bruck, Suttrop et al. 2011). TNFα inhibitors are considered ineffective or even harmful, and there are several cases of MAS following the use of etanercept in patients with AOSD (Stern, Riley et al. 2001, Gianella, Schaer et al. 2008). A multinational, multicentre study of treatment and outcome of MAS complicating SoJIA reported nearly all patients were treated with corticosteroids with 61% receiving cyclosporine. Biologic medications were given to 15% of the patients, with anakinra being the most frequently selected. Etoposide, which is a central medication in HLH therapeutic protocols was used in 11% of cases. It is argued that this may be too aggressive for use as first-line therapy in systemic JIA-associated MAS (Minoia, Davi et al. 2014).

SUMMARY POINTS

- Adult Still's disease (ASD) is a systemic inflammatory disorder of unknown aetiology, typically characterised by daily spiking high fevers, evanescent rash, arthritis and sore throat.
- ASD is a rare disorder with an incidence of approximately 0.2 per 100 000 people, with a bimodal peak at ages 15–25 and 36–46, and equal sex distribution.
- The aetiology of ASD is unknown. Some observations support a genetic predisposition, while various infectious triggers and alterations in cytokine production and innate immunity deficiency have also been suggested.
- Clinical manifestations of ASD include daily high spiking fever, evanescent salmon-pink macular rash, arthritis, sore throat, lymphadenopathy, hepatosplenomegaly, pleuritis, pericarditis, transient pulmonary infiltrates and haematological manifestations.
- The laboratory findings in ASD reflect the systemic inflammation and cytokine cascade present, and no finding is specific for ASD.
- ASD has been associated with marked elevations in serum ferritin concentrations with a low glycosylated fraction of ferritin ($\leq 20\%$).
- No radiographic finding is specific for ASD. The classic radiographic finding is bilateral non-erosive intercarpal and carpometacarpal joint space narrowing, progressing to bony ankylosis.
- Different sets of classification criteria can be used to establish a diagnosis of ASD. Most of these rely on the exclusion of other diseases.
- The clinical course of ASD can be divided into three main patterns with different prognoses: self-limiting or monophasic pattern, intermittent or polycyclic systemic pattern, and a chronic articular pattern with poor prognosis.
- There are no randomised, controlled, clinical trials assessing efficacy of treatment in ASD.
- The majority of patients with ASD will require glucocorticoids. In the presence of glucocorticoids resistance or dependence, a disease-modifying antirheumatic drug should be used and methotrexate is the preferred treatment.
- In patients with refractory or life-threatening ASD, biological agents should be considered off-label.
- Interleukin (IL)-1 and IL-6 blockers seem to be more effective than anti-tumour necrosis factor α agents (anti-TNF α). TNF α blockers and anti-IL-6 may be more useful in chronic polyarthritis. Anti-IL-1 and anti-IL-6 may be more effective in the presence of systemic manifestations.

2. Sarcoidosis

LEARNING OUTCOMES

- Outline the epidemiology of sarcoidosis
- Outline cellular and histological aspects of the pathogenesis of sarcoidosis
- Outline associations found in the aetiology of sarcoidosis in terms of environmental factors, genetics, cellular aspects and cytokines
- Describe the clinical manifestations of sarcoidosis in terms of pulmonary and extra pulmonary disease, especially musculoskeletal manifestations
- Describe and evaluate laboratory findings and imaging studies in sarcoidosis
- Describe how to achieve a diagnosis of sarcoidosis, initial evaluation and subsequent diagnostic procedures
- Describe the clinical course of sarcoidosis
- Describe treatment options in sarcoidosis, their indications and level of evidence

2.1 Introduction

Sarcoidosis is systemic inflammatory disease, characterised by non-caseating granulomas. Although primarily affecting the lungs, the disease is known for its myriad of presentations, frequently crossing the specialist boundaries of medicine. The earliest descriptions of sarcoidosis originate from Hutchinson, a 19th century London clinician with practices in internal medicine, dermatology, venereal disease, ophthalmology and surgery. In January 1858 Hutchinson encountered a 58-year-old coal wharf employee who presented with purple symmetrical skin plaques on his legs and hands that had developed gradually over the preceding 2 years. (Hutchinson 1877) To the best of our knowledge, this was the index case report of sarcoidosis in the medical literature.

This section will describe in detail the epidemiology, pathogenesis, aetiology, clinical manifestations, laboratory findings, imaging studies, diagnosis, course and treatment options of sarcoidosis.

2.2 Epidemiology

The exact prevalence and annual incidence of sarcoidosis are unknown, with studies reporting significant heterogeneity in incidence, prevalence, disease presentation and severity among different ethnic racial groups. Across Europe there is a greater incidence at higher latitudes (Sawahata and Sugiyama 2016), with Nordic countries reporting much higher incidence rates than other European countries (Hosoda, Sasagawa et al. 2002). Epidemiological studies from Africa are sparse and under-represented in the literature (Benatar 1977). The disease is more common in blacks than whites. In the United States the annual age adjusted incidence was 10.9 per 100 000 for white Americans and 35.5 per 100 000 for African-Americans (Rybicki, Major et al. 1997). It is rare among Asians (Morimoto, Azuma et al. 2008). Furthermore, the phenotypic expression and prognosis of the disease may vary by race. For example, blacks tend to present with more acute and severe disease, with eye, skin and bone marrow involvement, while white people may present with chronic disease and a higher prevalence of hypercalcemia (Ungprasert, Crowson et al. 2016).

Sarcoidosis occurs more frequently in adults younger than 40 years of age, with incidence peaking between 20 and 29 years (Gary W. Hunninghake 1999), although in recent decades, evidence has emerged of an upward shift in age at diagnosis (Sawahata and Sugiyama 2016). Several epidemiological studies have reported a second peak seen in women over the age of 50 (Hosoda, Sasagawa et al. 2002).

Familial clustering of sarcoidosis has repeatedly been reported since the 1920s. The prevalence of familial sarcoidosis (the rate of index having another member affected) ranges from 1.7% in the UK, 9.6% in Ireland and up to as high as 14%. (Hosoda, Sasagawa et al. 2002) In a case-control etiologic study of sarcoidosis the relative risk of sarcoidosis was estimated using first- and second-degree relatives. Cases were almost 5 times more likely than controls to report a first degree relative with sarcoidosis, although the absolute risk for having a relative with sarcoidosis was low. (Rybicki, Iannuzzi et al. 2001)

2.3 Pathogenesis

The immunopathogenesis of sarcoidosis is not completely understood, but likely represents disordered immune regulation in genetically predisposed individuals exposed to environmental triggers. The disease is characterised by the formation of epithelioid non-caseating granulomas which can affect any tissue in the body (figure 1). Humans generate granulomata whenever an antigen cannot be degraded and completely eliminated by its macrophages.

2.3.1 Granuloma

In sarcoidosis, an antigen is internalized by macrophages which process and present peptides to CD4 T cells via class II MHC molecules. Antigen presentation leads to CD4 T-cell activation. T cells and macrophages release cytokines or chemokines (IL-2, IL-12, IL-18, IFN- γ and TNF α) that amplify the Th1 response, leading to proliferation and recruitment. (Iannuzzi and Fontana 2011) The cytokine cascade induces cell–cell fusion between macrophages and monocytes/dendritic cells giving rise to multinucleated giant cells which organise into a cluster to form immature granuloma. (Hernandez-Pando, Bornstein et al. 2000, Sakthivel and Bruder 2016) (Agostini, Adami et al. 2000). As the granuloma develops, central areas become tightly packed with macrophages, epithelioid cells and multinucleated giant cells surrounded by a peripheral rim consisting of T cells, mast cells and fibroblasts. Epithelial cells are activated monocytes-macrophages which produce TNF α that mediates T cell activation and recruitment. Caseation is absent, although occasionally fibroid necrosis may be seen where several granuloma have coalesced (Van Gundy and Sharma 1987).

Figure 1 Sarcoid granuloma along a bronchiole (periodic acid–Schiff stain, $\times 100$) with inset (haematoxylin–phloxin–safran stain, $\times 1000$). (Source: CRI (Club Rhumatismes et Inflammation), <http://www.cri-net.com>)

2.3.2 Persistent Granuloma

In most cases granuloma resolve spontaneously, but in 20% to 25% of patients obliterative fibrosis may evolve with persistent granulomatous inflammation (Prasse, Pechkovsky et al. 2006, Zissel, Prasse et al. 2010). In these patients Th2 lymphocytes become the predominant type in the granuloma; they participate in inducing fibrous changes that begin at the periphery and migrate to the centre of the granuloma, ending with fibrosis and/or hyalinization.

The immunologic determinants of clinical remission versus chronic, unremitting sarcoidosis remain unknown. Several studies suggest that persistent inflammation results from inadequate regulatory T-cell function that is

deficient in suppressing TNF α or IFN- γ expression, whilst other studies have proposed an “exhausted” T-cell phenotype from repeated stimulation by pathogenic tissue antigens. (Chen and Moller 2015)

2.3.3 T cells populations

Within the granuloma the majority of lymphocytes are T helper (Th1) CD4+ T cells. The periphery of the granuloma is composed of CD4+ and T suppressor CD8+ T cells. Bronchoalveolar lavage (BAL) reflects this strong increase in cellularity with lymphocytic pleocytosis and predominance CD4+ T cells. In contrast peripheral blood demonstrates a T cell lymphopenia, a decrease number CD4+ T cell and a decreased CD4+:CD8+ T cell ratio, leading to decrease cell mediated immunity, and B cell hyperactivity. Significant lymphopenia has been correlated with disease severity. (Semenzato, Pezzutto et al. 1982, Forrester, Wang et al. 1994, Sweiss, Salloum et al. 2010)

The discovery of regulatory T cell classes has resulted in further evaluation of T cell phenotypes in sarcoid. Regulatory T cell (Treg) populations are elevated in BAL samples, but functionally defective. Th17 lymphocytes are a distinct subset of CD4+ cell that produce IL-17. These cells are present in both the early stage and in the progression towards the fibrotic phase of disease. A significant imbalance between these cell populations, an increase Th17:Treg ratio may contribute to the development of sarcoidosis. (Miyara, Amoura et al. 2006, Facco, Cabrelle et al. 2011)

2.3.4 Cytokines

Understanding the cytokine profiles of different diseases can help pinpoint aetiology and predict both biomarkers and also efficacious therapies. Sarcoidosis is associated with a highly polarised Th1 profile, reflected by increased levels of Th1 associated cytokines, chemokines and cytokine receptors and low Th2 associated cytokines in blood, BAL and sputum. TNF- α and IFN γ are fundamental to granulomatous inflammation and levels of both are elevated in sarcoid tissues. However multiple other cytokines also are important. These cytokines profiles would suggest that sarcoid is a T cell driven disease.

- IL-2 facilitates the expansion of the activated lymphocytes population. CD4+T cells possess IL-2 receptors. (Roth, Huchon et al. 1981, Girgis, Basha et al. 1995)
- IL-12 and IL-18 produced by macrophages act synergistically to stimulate CD4 T cells to produce IFN γ
- IL-6 stimulates T and B cell proliferation. IL-8 produced by macrophages is a strong neutrophil chemotactic factor. Elevated IL-6 and IL-8 levels in BAL fluid is associated with a BAL neutrophilia and a poor prognosis in sarcoidosis.(Shigehara, Shijubo et al. 2001)
- IL-15 produced by macrophages, co-acts with IL-2 in stimulating T and B cell proliferation, acting through the IL-2 receptor system. (Agostini, Trentin et al. 1996)

2.4 Aetiology

The reason why people develop sarcoid is unknown though both environmental and genetic factors are involved.

2.4.1 Genetics

Sarcoidosis can cluster in families, suggestive of a genetic contribution to its aetiology. A Scandinavian registry study of 210 twin pairs identified a higher risk for developing sarcoidosis in the co-twin of affected monozygotic (80-fold) and dizygotic (7-fold) twin siblings compared to the general population (Sverrild, Backer et al. 2008). Genetic associations with risk of developing sarcoidosis are frequently associated with the major histocompatibility complex. The first reported association was the with class I HLA-B8. (Brewerton, Cockburn et al. 1977) Since this, HLA class II antigens, HLA-DRB1 and DQB1 alleles have been more frequently associated (Iannuzzi, Maliarik et al. 2003, Rossman, Thompson et al. 2003), and subsequently specific pockets of HLA-DQ and HLA-DR have been reported as the most important regions involved. (Voorter, Amicosante et al. 2007, Chen and Moller 2015). These associations vary depending on the ethnic and racial makeup of the population studied and some associations are relatively weak, whilst not all have been validated. These findings suggest that the genetic background of an individual with sarcoidosis may account in part for the clinical heterogeneity seen in sarcoidosis.

2.4.2 Environmental risk factors

A number of environmental exposures, including infectious and inorganic, have been associated with the development of sarcoid.

2.4.2.1 Infection

The immunopathogenesis of sarcoidosis support an infectious aetiological hypothesis, and various probably inhaled micro-organism have been suspected but the evidence for specific pathogens varies significantly.

Löfgren's

Seasonal variation in the onset of sarcoidosis has been reported in both hemispheres with the highest prevalence in the cool summer or mild winter zones (Hosoda, Sasagawa et al. 2002). This is often cited as evidence for an infectious cause. Cases diagnosed during the springtime often present with Löfgren's Syndrome, with an acute onset, presence of erythema nodosum and often a favourable outcome.

Mycobacterium Tuberculosis (MTB)

The considerable histological and clinical similarities between sarcoidosis and mycobacterial disease, has led to extensive evaluation of MTB as an aetiological factor (Mangiapan and Hance 1995). A number of studies have

identified mycobacterial DNA within the sarcoid granuloma.(Mitchell, Turk et al. 1992, Saboor, Johnson et al. 1992). However this finding could not be confirmed in other reports (Wilsher, Menzies et al. 1998, Ishige, Usui et al. 1999, Matsui, Ohsumi et al. 2006). Interestingly the incidence and prevalence of sarcoidosis has not been reduced in countries where BCG vaccination is used.

Propionibacterium acnes

Propionibacterium acnes, a commensal bacterium, is capable of inducing a granulomatous reaction in experimental models. A multicentre study of lymph node samples detected *Propionibacterium* DNA by PCR analysis in 106 of 108 lymph nodes from patients with sarcoidosis. However, a significant number of controls also harboured propionibacteria DNA but in lower copy numbers. (Ishige, Usui et al. 1999). An antibody response to a *P. acnes* protein has been demonstrated in sarcoidosis BAL samples; however, the organism is also found in subjects without sarcoid. (Hiramatsu, Kataoka et al. 2003, Ishige, Eishi et al. 2005).

Viruses

Several different viruses, particularly herpes viruses, have been implicated as an inciting factor in sarcoidosis on the basis of serologic evidence. However, other studies have failed to confirm these findings. (Saidha, Sotirchos et al. 2012).

2.4.2.2 Environmental exposures

The association with specific occupations (agricultural workers and fire/rescue workers) has identified a link with environment factors. Studies have largely failed to identify other external exposures(Newman, Rose et al. 2004). Only beryllium is shown to produce granulomata similar to that seen in sarcoidosis.

Beryllium,

An immunological sensitization to beryllium salts manifest long after the cessation of chronic exposure to the inorganic metal. Beryllium causes chronic beryllium disease (CBD). This is defined by granulomatous inflammation in the lung, histologically indistinguishable from sarcoidosis, and the presence of mild to moderate thoracic lymph node enlargement.(Mayer, Hamzeh et al. 2014) (Müller-Quernheim, Gaede et al. 2006) Unlike sarcoidosis, systemic and extra-pulmonary manifestations are not characteristic. CBD is like a perfect phenocopy of sarcoidosis. With no widely accepted animal model of sarcoidosis some authors propose studying CBD to gain insights about the pathobiology of sarcoidosis.(Chen and Moller 2015).

September 11th World Trade Centre (WTC) collapse

There are reports of an increased incidence of sarcoidosis-like granulomatous pulmonary disease during the five years following the September 11th World Trade Centre (WTC) collapse. A case series reported 26 patients with

pathological evidence of new onset sarcoidosis following exposure to dust during the rescue and recovery (Izbicki, Chavko et al. 2007). A subsequent study in 2011 described post-9/11 sarcoidosis in 43 individuals from WTC health registry, noting musculoskeletal manifestations in over half of subjects (Jordan, Stellman et al. 2011). More than 400 substances were identified in airborne and settled samples of WTC. Potential agent(s) in this complex exposure could have triggered a sarcoidosis-like immune response.

Silicone breast implants

Lofgren syndrome and neurosarcoidosis have been reported in the context of silicone gel breast implants, sometimes years after insertion (Yoshida, Tanaka et al. 1996, Barzo and Tamasi 1998). Cutaneous inflammation and regional lymphadenopathy characterized by granuloma that contain silicone if examined appropriately (Vaamonde, Cabrera et al. 1997).

2.4.3 Kveim test

The Kveim test is an historic procedure that was considered diagnostic of sarcoidosis. An extract of sarcoid involved spleen from a donor was injected intradermally into a patient with suspected sarcoidosis. A raised papule would develop which was biopsied 6 week later with histological confirmation of sarcoid like granuloma. The test was considered confirmatory for the disease, demonstrating that a given individual was susceptible to granulomatous reactions when exposed to the appropriate antigen. However, subsequent studies of components of the reagent have not identified a responsible antigen (Siltzbach 1961). The Kveim test was used up until the 1990s when concerns about transmission of blood borne diseases led to its withdrawal.

2.5 Clinical manifestations

2.5.1 Pulmonary sarcoid

Pulmonary involvement is present in 90% of cases (Box 1). Patients may be asymptomatic and sarcoidosis can be detected incidentally on routine chest radiography.

Box 1. Pulmonary sarcoid - classification

Based on chest radiography findings, several stages of pulmonary involvement are distinguishable (Abril and Cohen 2004)

- **Stage 0: Normal radiograph**
- **Stage I: Bilateral hilar adenopathy without parenchymal involvement (figure 2(A))**
 - 50% present with bilateral hilar adenopathy as first expression of sarcoidosis.
 - Regression of hilar nodes occurs within 1-3 years occurs in 75%, whilst 10% will develop chronic enlargement that may persist for 10 years or more
- **Stage II: Bilateral hilar adenopathy with parenchymal involvement (figure 2(B))**
 - 5% present with these findings at initial diagnosis.
 - Two-thirds undergo spontaneous resolution, while in the remainder, the disease progresses or remains unchanged.

- **Stage III: Parenchymal involvement (reticular opacities) with shrinking hilar nodes**
 - Seen in 10%. Of these, approximately 14% have spontaneous remission
- **Stage IV: Pulmonary fibrosis**
 - reticular opacities with evidence of volume loss, predominantly in upper lung zones
 - traction bronchiectasis, calcification and cavitation or cyst formation may also be seen

Figure 2 (A) Stage I sarcoidosis with bilateral hilar adenopathy without parenchymal involvement in a 40-year-old man with Löfgren's syndrome. (B) Stage II sarcoidosis with bilateral interbronchial and laterotracheal adenopathy, diffuse micronodules with a predominance in the median region of the lung, sometimes confluent forming macronodules. (Source: CRI) <http://www.cri-net.com>

The most common pulmonary symptoms are cough and dyspnoea. Pulmonary sarcoid can affect the upper and/or lower airways. Upper respiratory tract involvement of sinuses, pharyngeal, vocal cord, tracheal and upper bronchus is less common, with an overall incidence of about 5%. (Baughman, Lower et al. 2010, Panselinas, Halstead et al. 2010) Lower bronchiole airflow obstruction occurs in a significant number of patients with sarcoidosis (Sharma and Johnson 1988, Baughman, Teirstein et al. 2001)

Adenopathy alone (or with parenchymal disease) is found in 50% of patients at diagnosis. (Baughman, Teirstein et al. 2001) It rarely leads to symptoms; however it may cause compression of a pulmonary artery or bronchial airway. Chest pain is common in pulmonary sarcoidosis, however there is no correlation between pain and adenopathy or pleural disease (Baughman, Lower et al. 2012)

Parenchymal disease occurs in a significant number of patients with sarcoidosis, with dyspnoea the most common symptom. (Baughman, Lower et al. 2012).

2.5.2 Extra pulmonary sarcoid

Sarcoidosis can involve all organ systems; 30% of patients have extra pulmonary disease. It may manifest in the musculoskeletal system, skin, eyes, reticuloendothelial system, exocrine and endocrine glands, heart, kidney and central nervous system. The frequency of extra-pulmonary manifestation varies with gender, age at presentation and ethnicity (Baughman, Teirstein et al. 2001)

2.5.3 Musculoskeletal manifestations

Musculoskeletal manifestations occur in up to 40% of patients with sarcoidosis, and include arthropathy, bone lesions, muscular disease and vasculitis

2.5.3.1 Acute arthritis (Löfgren's syndrome)

The most frequent musculoskeletal manifestation of sarcoidosis is an acute arthritis that occurs as part of Löfgren's syndrome. In 1953 Löfgren described 113 patients with the triad of symmetric hilar adenopathy, joint pain and erythema nodosum (Löfgren 1953).

The ankles are the most frequently involved joint, reported by Visser et al in 98% of patients with Löfgren's syndrome. It is bilateral in the majority (Visser, Vos et al. 2002). Joint involvement can extend to other sites including knees, wrist and elbows and metacarpophalangeal joints. On ultrasound imaging, joint swelling is usually attributable to periarticular soft tissue swelling and tenosynovitis. True joint synovitis or effusions are rare, and if present are usually minor and without power Doppler activity (Kellner, Spathling et al. 1992, Le Bras, Ehrenstein et al. 2014). Synovial fluid analysis reveals a mild inflammatory reaction with a predominance of mononuclear cells. Histopathological examination of the synovium typically does not demonstrate a granulomatous reaction (Pettersson 2000).

Chest radiographs reveal bilateral hilar adenopathy in 90% of patients, which is usually asymptomatic (Visser, Vos et al. 2002). Erythema nodosum is not universal, occurring in approximately 40%, reported more frequently

in Caucasians and women (Mana, Gomez-Vaquero et al. 1999, Grunewald and Eklund 2009). Fever and other constitutional symptoms may be present.

The natural course of Löfgren's syndrome is complete resolution, settling over a few months. In a minority of cases the duration until complete resolution is longer (18-24 months)(Mana, Gomez-Vaquero et al. 1999). Only a very small proportion experience relapse of the disease after resolution(Gran and Bohmer 1996, Mana, Gomez-Vaquero et al. 1999). Joint destruction in Löfgren's syndrome is extremely rare(Gran and Bohmer 1996).

2.5.3.2 Chronic arthritis

Chronic sarcoidosis related arthritis is uncommon (figure 3) and usually occurs with other complications of sarcoidosis, particularly skin involvement (Pettersson 1998, Abril and Cohen 2004, Chatham 2010, Sweiss, Patterson et al. 2010). The typical pattern is a symmetric medium to large joint oligoarthritis (Spilberg, Siltzbach et al. 1969, Visser, Vos et al. 2002). It is important to distinguish true synovitis from tenosynovitis, the latter being more frequently observed. Symmetric involvement of the extensor tendon compartment of the wrists should prompt suspicion of musculoskeletal sarcoidosis (Merle, Bour et al. 1986, González del Pino, Ulloa et al. 1997). Destructive arthritis is less frequently described(Sokoloff and Bunim 1959). Synovial fluid analysis reveals a milder inflammatory reaction compared to other arthritides, with a predominance of lymphocytes(Palmer and Schumacher 1984). Synovial biopsy may demonstrate non-caseating granulomas but is non-specific and other causes of synovial granuloma must be considered (e.g. mycobacterial infection).

Figure 3 Chronic arthritis in a young woman with sarcoidosis. (Source: CRI <http://www.cri-net.com>)

2.5.3.3 Jaccoud's

Jaccoud's arthropathy is characterized by the presence of a deforming, non-erosive arthritis. It is classically described in connective tissue disease, specifically systemic lupus erythematosus. Jaccoud's arthritis in sarcoidosis has been described in case reports (Sukenik, Hendler et al. 1991, Lima, Ribeiro et al. 2013). It usually presents in the context of extensive internal organ involvement, later in the course of the disease. Biopsy reveals fibrosis of the tendons with granulomas of epithelioid cells in the muscles and tendon sheets.

2.5.3.4 Axial disease

Spinal involvement in sarcoidosis is often asymptomatic and thus true prevalence is unknown. Vertebral lesions may be the initial presenting symptom, or can be identified incidentally when patients undergo isotope imaging for other reasons (e.g. to assess lung disease activity)(Rua-Figueroa, Gantes et al. 2002, Boyaci, Hornicek et al. 2012). Spinal lesions may appear lytic, sclerotic or both(Boyaci, Hornicek et al. 2012) and can involve any segment of spine(Rua-Figueroa, Gantes et al. 2002). Sacroiliitis in sarcoid is described in several case reports(Kötter, Dürk et al. 1995). While the prevalence in the general population of spondyloarthritis ranges from 1% to 1.9%, Erb et al. reported a 6% prevalence of spondyloarthritis in patients with sarcoidosis, suggesting a possible association between the two conditions(Erb, Cushley et al. 2005). Involvement may be unilateral and biopsy would typically confirm granulomatous disease(Kobak, Sever et al. 2014).

2.5.3.5 Dactylitis

Dactylitis is one of the most familiar appearances of musculoskeletal involvement in sarcoid. It is well documented in text books and most clinicians are familiar with this pattern of disease. However, it is actually quite uncommon. Dactylitis is almost exclusively associated with chronic systemic disease. It has been described in coexistence with lupus pernio and other forms of chronic cutaneous sarcoidosis. It typically develops in a symmetrical pattern, most often affecting the second and third phalanges, preserving the metacarpophalangeal joints(Awada, Abi-Karam et al.). Dactylitis is associated with swelling and erythema and similar in appearance to that in psoriatic arthritis(Rothschild, Pingitore et al. 1998). It is more common in Black-Americans. Histology confirms tenosynovitis and soft tissue granulomas. Radiographs tend to reveal cystic bone lesions, with a characteristic lattice like appearance(Pitt, Hamilton et al. 1983). Joint line erosions are not characteristic, although the cystic lesions can lead to articular collapse.

2.5.3.6 Myopathy

Skeletal muscle involvement has been estimated to occur in as many as half of all sarcoid patients(Silverstein and Siltzbach 1969), but is symptomatic in fewer than 3%(Wolfe, Pinals et al. 1987, Prayson 1999). Patients with

sarcoidosis frequently report generalized weakness, fatigue and reduced exercise capacity. Assessing the extent that such symptoms are attributable to respiratory disease versus muscle disease is often challenging (Marcellis, Lenssen et al. 2011). Sarcoid patients report myalgia more commonly than healthy controls (Hinz, Fleischer et al. 2011).

Three distinct clinical patterns of muscle involvement in sarcoidosis are recognized: chronic myopathy, nodular myopathy, acute myopathy. The chronic myopathy is the most common form, mainly reported in female patients between the age of 50 and 60 years. Clinically it manifests with insidious onset of symmetrical proximal muscle weakness; trunk and neck muscles can also be involved (Maeshima, Koike et al. 2015). Patients often have normal levels of muscle enzymes, whilst neurophysiology demonstrates myopathic changes comparable to other inflammatory muscle disorders (Wolfe, Pinals et al. 1987, Scola, Werneck et al. 2001). Muscle biopsy when performed, typically shows granulomatous change, alongside cellular infiltration with lymphocytes and macrophages with endomysial and perivascular inflammation (Prayson 1999, Le Roux, Streichenberger et al. 2007). Muscle tissue may be abnormal in patients without muscle symptoms, and represents a potential site for biopsy when other involved organs are less accessible to tissue diagnosis (figure 4). MRI may reveal muscle atrophy with fatty degeneration (Moore, Teirstein et al. 2005, Han, Jang et al. 2013). It is notable that some of the earlier MRI studies did not include fat suppression or STIR sequences, which have since been shown to be more sensitive to abnormalities. In more recent years FDG PET/CT has emerged as the most sensitive imaging technique for muscle involvement (Braun, Kessler et al. 2008, Cremers, Van Kroonenburgh et al. 2014).

The nodular form of sarcoid myopathy is characterized by the presence of single or multiple nodules in the muscles affected (Koyama, Ueda et al. 2004). Patients with this form of myopathy typically have symmetrical lower limb involvement (Fayad, Liote et al. 2006, Le Roux, Streichenberger et al. 2007). The nodules are often painful and over time can lead to muscle contractures. Serum levels of muscle enzymes and neurophysiology studies are within normal range. Macroscopic histological analysis demonstrates the location of the granulomatous lesions between the muscle bundles without direct involvement of the muscle fibres (Jamal, Cilursu et al. 1988, Fujimoto, Ikeda et al. 2002). MRI is a useful modality for localizing this pattern of myopathy (Aptel, Lecocq-Teixeira et al. 2015).

Acute myopathy is the least common form of sarcoid myopathy. It tends to occur early in the course of sarcoidosis and in patients younger than 40 years old (Le Roux, Streichenberger et al. 2007). The clinical presentation it's similar to other inflammatory myopathies with rapid onset of proximal weakness and myalgia associated with elevated creatinine kinase levels. Muscle biopsy confirms non-caseating granulomas with pronounced lymphocytic infiltration (Fujita, Ishimatsu et al. 2011).

Figure 4 Muscular localisation of sarcoidosis; MRI aspect. (Source: CRI <http://www.cri-net.com>)

2.5.3.7 Bone

Bone involvement is usually asymptomatic and often identified following imaging for other reasons (Neville, Carstairs et al. 1977). It is estimated to occur in 1-15% of patients with sarcoidosis (Neville, Carstairs et al. 1977). Bone involvement is seen in all ethnicities, although there is a suggestion of a racial predilection for the site of involvement, with bone cysts of the hands and feet more common in black people (Wilcox, Bharadwaj et al. 2000). Bone involvement is often accompanied by overlying skin disease. Soft tissue swelling and skin involvement predates bone abnormalities, observed up to four years prior to detectable radiologic changes (JAMES 1959). Three patterns of bone lesion are described in the literature: Permeative “moth-eaten” appearance, involving the cortex of the phalanges and accompanied by soft tissue swelling; Lytic lesions, also called bone cysts, which appear as cortical defect in the phalangeal heads or round punch out lesions; Sclerotic lesions, which are described in the spine and are similar to those seen in metastatic disease (Wilcox, Bharadwaj et al. 2000). Sarcoid bone lesions are more often cystic than sclerotic or lytic.

Bone involvement is reported most frequently in the proximal and middle phalanges, but the skull, nasal bones, maxilla, sternum, ribs, vertebra, pelvis, tibia and femur may also be affected. In the existing literature peripheral bone involvement is more frequently described, however increasing use of advanced imaging modalities (PET-CT or MRI) is revealing a higher proportion of patients with axial involvement. Sparks et al identified incidental sarcoidosis affecting the spine or pelvis in 90% of their cohort, while only 10% had isolated appendicular skeleton

involvement. In this study all patients had involvement in more than one bone site (Sparks, McSparron et al. 2014).

Bone lesions are usually detected by plain film radiography but in some cases may only be seen on MRI imaging. MRI has proven valuable in detecting silent disease, however there are no morphologic criteria to reliably distinguished osseous sarcoidosis from metastatic lesions (Moore, Teirstein et al. 2005).

Serum calcium or alkaline phosphatase levels are typically normal despite multiple affected bones. This finding reflects a distinct pathophysiology compared to other diseases, such as Paget's, malignancy, osteoporosis, or osteomalacia (Sparks, McSparron et al. 2014).

The presence of bone involvement is often suggestive of chronic severe sarcoidosis with multi-organ involvement. Bone lesions in themselves are not an indication for specific treatment unless symptomatic. Corticosteroids can ameliorate soft tissue swelling but do not improve the abnormal bone architecture (Johns and Michele 1999). Methotrexate and hydroxychloroquine have been used as corticosteroid sparing agents in bone disease with documenting varying success (Kaye, Palazzo et al. 1995). Case reports describe varying success with anti-TNF inhibitors for resistant cases (Garg, Garg et al. 2008, Hasni, Kunz et al. 2010).

2.5.3.8 Vasculitis

Vasculitis is very rare in sarcoidosis, but it may be the presentation symptom and can be life threatening. It has been reported in the form of leukocytoclastic vasculitis and affecting small, medium or large arteries, and granulomatous vasculitis. (Fernandes, Singsen et al. 2000)

2.5.4 Dermatological manifestations

Involvement of the skin can occur in up to 30% of patients with sarcoidosis, and is often a presenting feature. Lesions may be asymptomatic and therefore careful dermatologic examination is an essential component of assessment in suspected sarcoidosis. When present, lesions are characterised by the presence of granulomas on histopathological examination (Elgart 1986, Roberts, Mirowski et al. 2004).

- *Papular sarcoidosis*: common finding of numerous, 1 to 10mm papules located on the face with a predilection for the eyelids and nasolabial folds. Coalescence may lead to the formation of plaques.
- *Maculopapular sarcoidosis*: slightly hyperpigmented patches around 1 mm in diameter.
- *Nodular sarcoidosis*: waxy pink nodular lesions on face, trunk and extensor surface of extremities. It can affect the subcutaneous tissue commonly located on the upper extremities.

- *Lupus pernio*: violaceous indurated plaques or nodules distributed on the central face, usually nasal tip, and cheeks, ears and lips. It is associated with chronic disease and pulmonary fibrosis (figure 5).
- *Erythema nodosum*: erythematous, tender, subcutaneous plaques and nodules predominantly located on the anterior tibial areas.(Neville, Walker et al. 1983) Histopathologic findings are consistent with a septal panniculitis.
- Other atypical findings include ulcerative, psoriasiform, hypopigmented, follicular, angioid, rosacea-like or morpheaform lesions

Figure 5. *Lupus pernio*. (Source: CRI <http://www.cri-net.com>)

2.5.5 Ophthalmologic manifestations

Eye involvement occurs in up to 25% of patient with sarcoidosis and is the presenting feature in 5%. Several ophthalmologic manifestation of sarcoidosis can occur:

- Anterior uveitis
- Posterior uveitis
- Retinal vasculitis
- Keratoconjunctivitis
- Conjunctival follicles
- Scleritis (very rare)

The most common ocular manifestations are uveitis (30–70%) and conjunctival nodules (40%). Uveitis is subclinical in up to 80% of cases and as such patients with sarcoidosis should undergo ophthalmic evaluation(Abril and Cohen 2004). Anterior uveitis may either present as acute iridocyclitis, commonly seen in

Löfgren's syndrome, or as a chronic granulomatous uveitis with keratic precipitates, which may vary from cellular to large 'mutton fat' type (Umur, Tayfun et al. 2012, Liu and Birnbaum 2015) (Figure 6).

Anterior uveitis may resolve spontaneously or with the use of local corticosteroids, but posterior uveitis requires systemic treatment. Untreated this may progress to cause secondary glaucoma, cataract and blindness. Blindness can occur in 20% of patients with ophthalmic sarcoid.

Figure 6 'mutton fat' keratic precipitates (Source: <http://webeye.ophth.uiowa.edu/eyeforum/atlas>)

2.5.6 Reticuloendothelial manifestations

Reticuloendothelial manifestations are common in sarcoidosis. Up to 40% have peripheral lymphadenopathy and 25% have splenomegaly, of which 80% have splenic granulomata (figure 7). Massive splenomegaly is rare. Hypersplenism may cause anaemia, leukopenia and thrombocytopenia.

Hepatic involvement affects the majority of patients with sarcoid, although the clinical consequences of involvement are variable. Most patients are asymptomatic with only biochemical abnormalities. Hepatomegaly is present in up to 20%, with jaundice in less than 5%. The liver is homogeneous in appearance, but hypoattenuating nodules may rarely be seen which are reported as liver granuloma on biopsy. (Warshauer and Lee 2004). Rarely cirrhosis or cholestatic liver disease may occur. (Devaney, Goodman et al. 1993)

Figure 7 Splenic localisation of sarcoidosis. (Source: CRI <http://www.cri-net.com>)

2.5.7 Exocrine manifestations

Sarcoidosis may involve the exocrine glands in 3-9% of patients. (Abril and Cohen 2004). Painful or painless swelling of the salivary glands occurs in approximately 4%, and is self-limiting in 40%. Keratoconjunctivitis and salivary gland involvement in sarcoid may resemble Sjögren's syndrome or IgG4 disease. Heerfordt's syndrome is the combination of anterior uveitis, parotid gland involvement, facial palsy and fever. Sarcoid pancreatitis can also occur.

2.5.8 Endocrine manifestations

Endocrine involvement in sarcoidosis includes hypothalamic involvement from basilar granulomatous meningitis, and sometimes hormonal changes may be the first manifestation of a neural sarcoid. Hypothalamic infiltration is the predominant cause for endocrine abnormalities, which include more commonly, diabetes insipidus, adenopituitary failure or amenorrhea-galactorrhoea syndrome (Murialdo and Tamagno 2002).

Sarcoidosis can involve the testes and cause recurrent epididymitis although this is rare. Testosterone level may be reduced due to a dysfunctioning hypothalamus-pituitary-gonadotrophic axis, systemic inflammation or a side effect of corticosteroid therapy (Spruit, Thomeer et al. 2007). Sarcoid rarely involves the female genital tract and in the absence of severe disease, it does not affect fertility or the incidence of foetal or obstetrical complications (Selroos 1990). It will often improve during pregnancy possibly due to increases of maternal free cortisol.

Sarcoidosis can cause diffuse goitre or rarely a solitary thyroid nodule. Almost all patients are euthyroid (Porter, Beynon et al. 2003)

2.5.9 Gastrointestinal manifestations

Clinically recognisable gastrointestinal disease occurs in 0.1 to 0.9%, although the incidence of subclinical involvement may be greater. The stomach is the most commonly involved portion with peptic ulceration or narrowing of the gastric lumen due to granulomatous inflammation and associated fibrosis of the gastric wall. However, sarcoidosis of the oesophagus, appendix, colon, and rectum has also been described. Small bowel involvement is very rare. (Sprague, Harper et al. 1984, Dulai and Rothstein 2012).

2.5.10 Metabolic and renal manifestations

The most common electrolyte disturbance among patients with sarcoidosis is an abnormality of calcium metabolism, due to extra renal non-regulated hyperproduction of 1,25(OH) D₃ by activated macrophages in the granuloma. This primarily increases intestinal calcium absorption causing hypercalcemia (10-20% of cases), hypercalciuria (50% of cases), nephrocalcinosis and nephrolithiasis. (Inui, Murayama et al. 2001) If untreated, persistent renal calcium deposition may lead to renal failure. High 1,25(OH) D₃ also induces osteoclast activation and bone resorption increasing the risk of osteoporosis.

Primary renal manifestations are nephrolithiasis and nephrocalcinosis and acute interstitial nephritis with or without granuloma formation. The classic renal lesion of non-caseating granulomatous interstitial nephritis rarely causes clinically significant renal disease. It is commonly found on the initial presentation of sarcoidosis. The diagnosis is suggested by an elevated creatinine and bland urinary sediment. Renal biopsy reveals normal glomeruli, mononuclear cell infiltration, interstitial infiltration with non-caseating granulomas and tubular injury. These findings are suggestive, but not diagnostic of sarcoidosis. (Berliner, Haas et al. 2006) Other renal complications of sarcoidosis include membranous nephropathy, proliferative or crescentic glomerulonephritis, focal segmental glomerulosclerosis or polyuria due to diabetes insipidus.

2.5.11 Cardiovascular

Granulomas may involve all layers of the heart and both ventricles and atria. The most commonly affected area is the left ventricular free wall, particularly at the base, followed by the basal interventricular septum. Clinical manifestations relate primarily to the location and inflammatory effects of the granulomas. (Skali, Schulman et al. 2013)

Infiltration of the ventricular septum and conduction system may lead to ventricular tachyarrhythmias or conduction block and sudden death. Complete heart block is the most common finding in patients with clinically evident cardiac sarcoidosis. Ventricular arrhythmias are the second most common presentation arising when sarcoid granulomas within the myocardium become foci for abnormal automaticity, or may disrupt ventricular activation and recovery causing re-entrant arrhythmias. Electrocardiography reveals ventricular arrhythmias in 22% of patients. (Yoshida, Morimoto et al. 1997). It is important to perform Holter ECG and echocardiogram if

cardiac involvement is suspected (Chapelon-Abric, de Zuttere et al. 2004), although standard cardiac imaging may be normal despite disease.

Extensive granulomatous infiltration of the myocardium can cause both systolic and diastolic dysfunction. Patients may present with heart failure or dilated cardiomyopathy (Yazaki, Isobe et al. 1998). Unlike with other infiltrative cardiomyopathies, myocardial involvement in sarcoidosis is typically patchy. An endomyocardial biopsy can confirm the diagnosis, however, this carries risks and lacks sensitivity given the heterogeneous myocardial involvement. Cardiac MRI or FDG PET are non-invasive techniques to aid diagnosis and may help in assessing disease activity and response to treatment. (Skali, Schulman et al. 2013).

Sarcoidosis may cause cor pulmonale secondary to advanced fibrotic pulmonary disease.

2.5.12 Neurological

Neurologic complications occur in approximately 5-10% of patients with sarcoidosis (Baughman, Teirstein et al. 2001, Burns 2003, Terushkin, Stern et al. 2010). The central (figure 8) or peripheral nervous system can be affected. Manifestation may occur early in the disease and sometimes are severe and may be life threatening (Nozaki and Judson 2012).

Granulomatous inflammation in a perivascular distribution of the brain can produce focal or generalized seizures, or an encephalopathy or vasculopathy. Patients may present with cognitive or psychiatric problems and/or focal neurologic deficits. In rare cases, this manifests as a focal cerebral infarction (Navi and DeAngelis 2009). Meningeal involvement can present as an acute aseptic meningitis or a chronic meningitis, and meningeal mass lesions are reported. Communicating or non-communicating hydrocephalus may develop acutely or sub acutely. (Brouwer, de Gans et al. 2009) A myelopathy or radiculopathy can occur if granulomatous inflammation affects the spinal cord.

Neuroendocrine dysfunction may occur with hypothalamic infiltration. Cranial mononeuropathy may occur; a peripheral facial nerve palsy develops in 25-50% of patients with neurosarcoidosis (Stern, Krumholz et al. 1985).

Peripheral neuropathy is seen in later stages of disease and associated with poor response to treatment. These include mononeuropathy, mononeuritis multiplex, sensory, small fibre sensory, sensorimotor, autonomic and motor polyneuropathies. (Zuniga, Ropper et al. 1991). Electromyography reveals an axonal neuropathy.

Figure 8 Brain sarcoidosis localisation; MRI aspect. (Source: CRI <http://www.cri-net.com>)

2.6 Investigations

A comprehensive assessment should be performed in cases of suspected sarcoidosis to obtain additional evidence supporting the diagnosis, exclude alternative diagnoses and identify the degree of organ involvement.

2.6.1 Laboratory

A variety of laboratory abnormalities may be seen in patients with sarcoidosis:

- Anaemia occurs in 4-20% of patients. It usually results from the anaemia of chronic disease, although may also be due to hypersplenism, autoimmune haemolytic anaemia or bone marrow involvement. (Lower, Smith et al. 1988)
- Leukopenia, and more precisely lymphopenia occur in 40% of patients, eosinophilia may be seen (Renston, Goldman et al. 2000) while thrombocytopenia is rare.
- The erythrocyte sedimentation rate is frequently raised but is not useful in assessing disease activity.
- C-reactive protein (CRP) may be mildly elevated in one third of patients with sarcoidosis
- Hypercalciuria occurs in 50% of cases, hypercalcemia in 10-20%
- A moderate elevation in serum alkaline phosphatase concentration suggests diffuse granulomatous hepatic involvement
- Hypergammaglobulinaemia

2.6.1.1 Serological markers

Certain serologic markers have been identified which may play a role in diagnosis or monitoring disease activity:

Angiotensin converting enzyme (ACE) :

Serum ACE is produced by epithelioid cells and macrophages within the granulomata. It may participate in granuloma formation by producing angiotensin-II which is chemotactic for macrophages. The ACE level is elevated in 40-90% of untreated chronic sarcoidosis. (Abril and Cohen 2004). However, levels are frequently normal in acute disease. Some patient with active pulmonary sarcoidosis may have elevated levels which decrease with successful treatment. However serum ACE has limited utility as a diagnostic test, due to poor sensitivity and insufficient specificity (10% false positive results) (Ungprasert, Carmona et al. 2016). It may have a limited role in supporting the diagnosis of sarcoidosis in the situation where the pre-test probability is high.

Soluble interleukin-2 receptor (sIL2R) :

Cytokines IL1 and IL-6 stimulate macrophages to produce IL-2 which activate T-cells. Active T-cell surfaces possess IL-2 receptors and after activation, a soluble chain of the IL-2R is released. It has been reported that sIL2R increases in the active sarcoidosis and may be a useful marker for determination of extra pulmonary involvement in sarcoidosis patients (Grutters, Fellrath et al. 2003, Rothkrantz-Kos, van Dieijen-Visser et al. 2003, Gungor, Ozseker et al. 2015).

2.6.1.2 Lumbar puncture

Cerebrospinal fluid (CSF) fluid results characteristically demonstrate an elevated raised total protein in 2/3rd of patients, typically up to 250 mg/dL and a pleocytosis in approximately 50%. CSF ACE concentration is occasionally elevated, but reliable normal values are lacking. (Joseph and Scolding 2009)

2.6.2 Imaging

2.6.2.1 Chest radiograph (See above)

2.6.2.2 Chest computed tomography

High resolution computed tomography (HRCT) of the chest may typically reveals lung parenchymal changes in mid-to-upper zone predominance (figure 9). Findings may include:

- Hilar and mediastinal lymphadenopathy
- Beaded or irregular thickening of the Broncho vascular bundles
- Nodules along bronchi, vessels, and sub pleural regions
- Bronchial wall thickening
- Ground glass opacification

- Parenchymal masses or nodular consolidation, occasionally with cavitation
- Parenchymal bands / cysts
- Fibrosis with distortion of the lung architecture and traction bronchiectasis

Figure 9 High-resolution CT scan. A) Diffuse micronodules with a lymphatic distribution. Macronodules are formed by the confluence of micronodules. B) Same patient, with complete resolution of the lesions with steroids. These lesions are all potentially reversible with treatment. (Source: CRI <http://www.cri-net.com>)

2.6.2.3 Joint and bone

Plain radiographs in sarcoid bone involvement may show cystic lytic or sclerotic bone lesions. Most frequently the proximal and middle phalanges are affected, but other bone may be involved (figure 10).

Figure 10 A. Bone sarcoidosis. Lytic lesions of different size in toe phalanges. B. Chronic arthritis in a young woman with sarcoidosis. (Source: CRI <http://www.cri-net.com>)

2.6.2.4 Isotope imaging

PET imaging has superseded other radiotracer scan techniques in the evaluation of sarcoidosis. ¹⁸F-FDG PET may be useful for evaluating the extent of sarcoidosis and recognising lesions at different sites which may be more accessible to biopsy (figure 11). However, it does not differentiate sarcoidosis from malignancy as ¹⁸F-FDG PET may be positive in both processes, with elevations of standardized uptake value (SUV) into the “malignant” range (Teirstein, Machac et al. 2007, Braun, Kessler et al. 2008). The use of other tracers that can differentiate sarcoidosis may improve the utility of this imaging modality in the future. FDG-PET can detect active cardiac sarcoidosis with high sensitivity but has lower specificity as uptake is seen in other inflammatory myocardial diseases. (Skali, Schulman et al. 2013).

Radiotracer-based scanning using gallium-67 citrate or technetium-99m bisphosphonate may be useful in localising inflammatory foci, detecting active alveolitis, and assessing the response to treatment. However increased uptake in the lungs is not specific for sarcoidosis and a negative scan does not exclude disease (Baughman, Shipley et al. 1987). Gallium scans may show the combination of the "panda" and "lambda" signs that are useful in the diagnosis of sarcoidosis if none of the sites of disease are amenable to biopsy (figure 12 and 13). The "panda" sign occurs with bilateral uptake in the lacrimal and parotid glands is superimposed on the normal uptake by the nasopharyngeal mucosa. The "lambda" sign refers to gallium uptake by the right Paratracheal and bilateral hilar lymph nodes results in a pattern similar to the Greek "lambda" symbol.

Figure 11: ¹⁸F-FDG-PET/CT imaging in a patient with sarcoidosis. Intense uptake in the hilar lymph nodes and muscle.

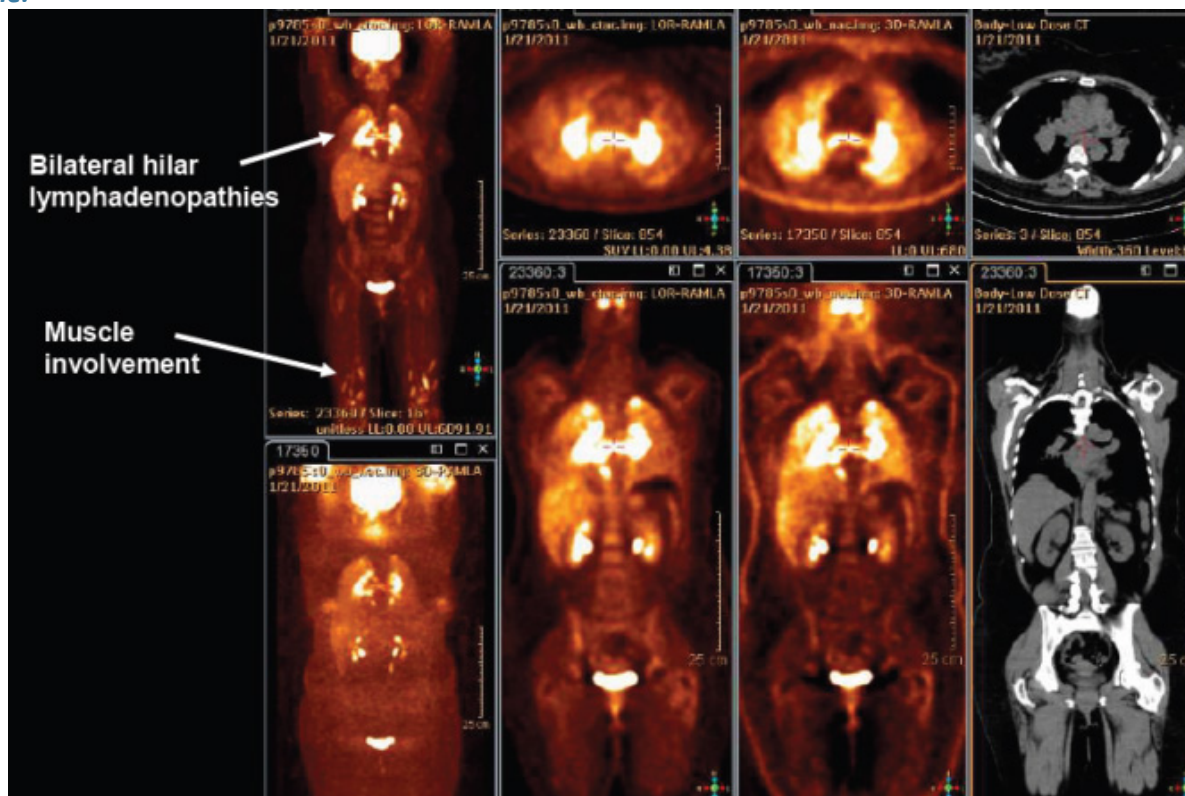

Figure 12 Bilateral hilar lymph nodes on gallium scintigraphy at 72 h. (Source: CRI <http://www.cri-net.com>)

Figure 13 Gallium scintigraphy in a patient with sarcoidosis. Strong uptake in the lachrymal glands, the parotid and submaxillary glands and in the pituitary mucosa (panda sign). Intense uptake in the hilar lymph nodes and in right axillary lymph nodes. (Source: CRI <http://www.cri-net.com>)

2.6.3 Pulmonary function test

Pulmonary function tests assess severity of respiratory impairment and serial measurements monitor the course of disease. They characteristically reveal a restrictive pattern (reduced vital capacity and total lung capacity) associated with a reduction in the diffusing capacity for carbon monoxide (DLCO)(Dunn, Watters et al. 1988). Although endobronchial sarcoidosis may lead to an obstructive pattern.

2.6.4 Bronchoalveolar Lavage (BAL)

In sarcoidosis BAL is used to exclude infections and malignancy as alternative diagnoses, but can also be used as an adjunctive to support the diagnosis. A lymphocytosis is common (30-50% lymphocytes), with reduced number of CD8 cells, elevated CD4:CD8 ratio (>3.5) and an increased number of activated T cells, CD4 cells, immunoglobulins, and IgG-secreting cells.

2.6.5 Histology

Histological proof is not required in patients presenting with classical Lofgren syndrome, although diagnostic yield from lymph node or lung biopsy is $>90\%$. For all other patients with suspected sarcoidosis, tissue is usually required to confirm diagnosis. If no easily accessible lesion is available, bronchoscopy with ultrasound guided trans bronchial lung biopsy may be considered (von Bartheld, Dekkers et al. 2013). Synovial tissue biopsy may be warranted in the diagnosis of sarcoid arthropathy, the findings of sterile non-caseating granulomatous inflammation on biopsy is supportive but not diagnostic. Liver biopsy is not recommended as liver granulomata occur in a variety of other liver disorders (Awada, Abi-Karam et al.) nor is biopsy of erythema nodosum.

The characteristic morphologic feature of sarcoidosis is the non-caseating granuloma. The appearance of the granuloma in sarcoid is not distinguishable from those observed in other granulomatous disorders, although the presence of asteroid bodies is supportive (figure 14)(Iwai, Tachibana et al. 1993, Costabel, Hunninghake et al. 1999, Heinle and Chang 2014). Certain infections including tuberculosis mycobacterium, inflammatory bowel disease, systemic vasculitis and lymphoproliferative disorders are established causes of granulomatous inflammation, all of which have musculoskeletal manifestations. Granulomas occurring outside of the typical syndromes associated with sarcoid should arouse suspicion of alternative diagnoses.

Figure 14 Haematoxylin and eosin stained bone marrow specimen showing pink star shaped inclusion in clearing within granuloma. Figure courtesy of Dr. Jon Salisbury.

2.7 Diagnosis

There are no specific diagnostic tests for sarcoidosis. The diagnosis relies on a combination of clinical and radiological manifestations, histological proof of non-caseating granulomata and exclusion of other diseases with similar presentations

2.8 Course

There is no known cure for sarcoidosis however the spontaneous remission occurs in 60–70% of cases, most frequently in Löfgren's syndrome (Awada, Abi-Karam et al.), and if the disease persists it may not cause sufficient symptoms or injury to require therapy. However, a substantial minority do develop progressive disease with concomitant morbidity, and a small proportion might present with life threatening manifestations. Adverse prognostic factors are outlined in Box 2. Reported mortalities in sarcoidosis vary from 1% to 7 % depending on the setting and population studied. (Reich 2002, Gribbin, Hubbard et al. 2006, Nicholson, Plant et al. 2010, Tukey, Berman et al. 2013). Insight regarding the prognosis influences treatment decisions.

Box 2. Adverse Prognostic Factors (Awada et al., Wijsenbeek and Culver 2015)

- Black origin
- Age of onset after 40
- Pulmonary:
 - pulmonary hypertension,
 - significant lung function impairment,
 - moderate to severe dyspnoea,
 - BAL neutrophilia
- Extra pulmonary :
 - Cardiac involvement
 - Neurosarcoidosis (except isolated CN palsy)
 - Chronic hypercalcaemia / Nephrocalcinosis
 - Splenomegaly
 - Osseous disease
 - Lupus pernio
 - Chronic uveitis

2.9 Treatment

Treatment of sarcoidosis should be based on extent, severity and activity of disease and the impact on the patient's life. Indications for therapy are outlined in Box 3 (Wijsenbeek and Culver 2015)

Box 3. Indication for therapy (Wijsenbeek and Culver 2015)

- **Respiratory:**
 - Symptomatic pulmonary disease with infiltrates
 - Progressive deterioration of pulmonary function tests
 - Significant upper respiratory tract sarcoidosis
- **Musculoskeletal:**
 - inflammatory joint or tendon disease
 - active focal or acute myopathy
 - progressive symptomatic bone lesions
- **Ocular:**
 - Posterior or intermediate uveitis
 - Anterior uveitis refractory to topical therapy or with toxicities from topical therapy
- **Cutaneous :**
 - Disfiguring lesions (patient choice)
- **Hepatic :**
 - Impaired synthetic function
 - Hyperbilirubinemia
 - Progressive increase of transaminase levels
 - Portal hypertension
- **Splenic :**
 - Pain or early satiety caused by enlargement
 - Cytopenias caused by hypersplenism
- **Cardiac :**
 - Second-degree or third-degree conduction block
 - Ventricular dysrhythmias
 - Cardiomyopathy
 - *Treatment of diastolic heart failure and supraventricular dysrhythmias is unclear*
- **Neurologic :**
 - Any brain or spinal cord involvement
 - Granulomatous peripheral nerve disease
 - *Possible exceptions: isolated cranial nerve VII palsy, mild acute aseptic meningitis*
- **Bone marrow :**
 - Cytopenia
- **Endocrine :**
 - Significant hypercalcemia/hypercalciuria
 - Nephrolithiasis
 - Pituitary sarcoidosis

2.9.1 Corticosteroids

The first line systemic treatment is corticosteroids, which suppress the pro-inflammatory cytokines and chemokines involved in cell-mediated immune responses and granuloma formation. (16) Corticosteroid act by reducing gene transcription of inflammatory genes, *e.g.* IL-1 and TNF- α , adhesion molecules and receptors, by interaction with pro-inflammatory transcription factors nuclear factor- κ B (NF- κ B). 10–100 genes are thought to

be directly or indirectly regulated by corticosteroids. (Drent, van den Berg et al. 2001, Grutters and van den Bosch 2006).

2.9.1.1 Corticosteroids in pulmonary sarcoid

For pulmonary sarcoid, the balance of evidence suggests that oral glucocorticoids improve respiratory symptoms and radiographic abnormalities, although not necessarily pulmonary function tests (Paramothayan, Lasserson et al. 2005). End stage fibrosis is not responsive to immunosuppressive therapy. While the optimal dose is not known, the following treatment schedule has been recommended (Schutt, Bullington et al. 2010). Inhaled corticosteroids may be used for symptomatic cough.

Initial treatment:

- Daily dose: 0.3-0.6 mg/kg (20-40 mg/day) for 4-6 weeks.
- If disease parameters are stable or improved, the dose is tapered by 5-10 mg decrements every 4-8 weeks down to 0.2-0.4 mg/kg (10-20 mg/day)
- If the disease parameters are unimproved, the initial dose is continued for another 4-6 weeks.
- Higher doses (80-100 mg/day) may be warranted in acute respiratory failure or cardiac, neurologic, ocular or upper airway disease.

Maintenance therapy:

- There are no formal data to guide maintenance dosing. Based on clinical experience, a maintenance dose of 0.25-0.5 mg/kg (10-20 mg) will prevent worsening of disease.
- This is continued for six to eight months, providing a total treatment period of about 1 year, where the majority are able to discontinue systemic glucocorticoids.
- 1/3rd may relapse and require another course of therapy, whilst a minority may require long-term or indefinite maintenance therapy to control their symptoms

2.9.1.2 Corticosteroid in musculoskeletal sarcoid

Löfgren's syndrome is a self-limiting process and in many circumstances non-steroidal-anti-inflammatory drugs (NSAIDs) are sufficient (Baughman and Lower 2014). For systemic disease, corticosteroids are the mainstay of treatment. Where corticosteroids are used to treat articular manifestations, prednisolone 10-20mg is usually sufficient to control acute arthritis, and in patients with chronic disease lower doses are acceptable (Sweiss, Patterson et al. 2010).

There are no randomized controlled trials of treatments in sarcoid myopathy. Corticosteroids are widely used with the same regimes used for other inflammatory myopathies. They are generally efficacious in acute and

nodular muscular sarcoidosis, although less so in chronic sarcoid myopathy. The earlier the treatment, the more effective it is. However despite initial success a high rate of relapse is reported (Fayad, Liote et al. 2006). Intralesional injections of triamcinolone have been successfully administered for painful nodular lesions (Janssen, Dijkmans et al. 1991).

2.9.2 Methotrexate (MTX)

Immunosuppressive drugs are used in corticosteroids refractory disease or in those who require high doses of steroids for prolonged periods.

The World Association of Sarcoidosis and Other Granulomatous Disorders (WASOG) advocates methotrexate as first choice drug for progressive lung disease (Cremers, Drent et al. 2013). However, the evidence is limited and largely observational (Lower and Baughman 1990, Suda, Sato et al. 1994, Agbogu, Stern et al. 1995, Kaye, Palazzo et al. 1995, Baughman, Winget et al. 2000). One small randomised trial, several small series, and case reports suggest efficacy in lungs, skin, eyes, and neurological disease. Response rates are around 40-60% (Lower and Baughman 1995). Baughman et al demonstrated MTX effectiveness in a randomized control study as corticosteroid sparing in the first year of corticosteroid therapy in acute sarcoidosis (Baughman and Lower 1999). Vorselaars et al compared azathioprine versus MTX in a retrospective cohort study and suggested significant steroid-sparing potency and comparable side effects, except for a higher infection rate in the azathioprine group (Vorselaars, Wuyts et al. 2013).

MTX dose administration and monitoring is similar to those in rheumatoid arthritis. However MTX associated liver fibrosis may occur more frequently in sarcoidosis, seen in up to 10% receiving long term treatment (Baughman and Lower 1999). MTX-associated interstitial pneumonitis resulting in pulmonary fibrosis is rare but may be difficult to distinguish from progressive interstitial lung changes secondary to sarcoidosis (Baughman and Lower 1999).

There are, however, no trials of methotrexate use in sarcoidosis arthritis. The choice of steroid sparing agent is largely without an evidence base. Although positive case reports exist publication bias is likely. (Kaye, Palazzo et al. 1995, Baughman and Lower 1999, Braun and Rau 2009).

2.9.3 Azathioprine

Azathioprine is used as second line therapy for pulmonary sarcoidosis in patients who have failed MTX. It is used in combination with glucocorticoids rather than as monotherapy. There are no randomized trials although efficacy has been demonstrated in two open-label series (Pacheco, Marechal et al. 1985, Muller-Quernheim, Kienast et al. 1999).

2.9.4 Leflunomide

Leflunomide has been evaluated in 2 retrospective series involving a total of 108 patients (Baughman and Lower 2004, Sahoo, Bandyopadhyay et al. 2011). Baughman et al demonstrated leflunomide to be as effective as MTX in ocular and pulmonary disease when used alone or in combination with methotrexate (Baughman and Lower 2004). Leflunomide has also been successfully used as an alternative or addition to methotrexate in facilitating steroid dose reduction in both pulmonary and extra pulmonary disease (Sahoo, Bandyopadhyay et al. 2011). Leflunomide seems to be most effective when used in combination with MTX.

2.9.5 Mycophenolate

MMF does not appear to provide extra benefit in sarcoidosis patients that are unresponsive to previous corticosteroid-sparing agents. The largest series of mycophenolate therapy in pulmonary sarcoid included 37 patients (Hamzeh, Voelker et al. 2014). There was no statistically significant improvement in lung function although the mean daily prednisone dose was successfully tapered. Case reports and a small series have suggested a role for MMF in neurosarcoid especially with CNS involvement (Androdias, Maillet et al. 2011). Lastly, there is some reported efficacy in renal sarcoidosis, which is useful as mycophenolate is safer in those with poor renal function (Moudgil, Przygodzki et al. 2006).

2.9.6 Antimalarial agents

Hydroxychloroquine has been used successfully for patients with cutaneous sarcoidosis (Jones and Callen 1990, Doherty and Rosen 2008). A systematic review prior to 2004 found 82% treated with chloroquine or hydroxychloroquine had a favourable response to therapy (Zic, Horowitz et al. 1991). To date, no comparative studies are available.

2.9.7 Other therapies

Cyclophosphamide, chlorambucil, and thalidomide are medications that have been used historically, although are less commonly used in contemporary practice. Apremilast has some efficacy in cutaneous sarcoidosis. (Baughman, Judson et al. 2012)

2.9.8 Biologics

Tumour necrosis factor alpha (TNF- α) plays a pivotal role in maintenance of granulomas formation in sarcoidosis, and thus is a potential therapeutic target. Despite positive case reports and series, randomized control trials, especially in pulmonary disease have been disappointing.

2.9.8.1 Infliximab

Infliximab has been use in patients with pulmonary and extra pulmonary sarcoidosis refractory to corticosteroids in case reports and small case series with success. (Baughman and Lower 2001, Ulbricht, Stoll et al. 2003,

Pritchard and Nadarajah 2004) (Hostettler, Studler et al. 2012). Randomised controlled trial data has been disappointing. Baughman et al reported an improvement in predicted FVC% in 138 patients with chronic pulmonary sarcoidosis. However the effect size was small and clinically insignificant (Baughman, Drent et al. 2006). Rossman et al reviewed 19 patients with active pulmonary sarcoidosis resistant to corticosteroids and did not demonstrate any significant benefit in lung function. (Rossman, Newman et al. 2006). A RCT in extra pulmonary disease demonstrated a modest improvement in the infliximab group, although this was not maintained during the 24 month follow-up period. (Judson, Baughman et al. 2008). There are suggestions that a subset of patient with peripheral blood CD4 T cell lymphopenia may be more likely to respond to infliximab (Crouser, Lozanski et al. 2010).

2.9.8.2 Etanercept

Etanercept has failed to demonstrate efficacy in sarcoidosis. A study in pulmonary sarcoidosis was terminated after the enrolment of 17 patients as interval assessment noted treatment failure in 11 patients (Utz, Limper et al. 2003). In refractory ocular sarcoidosis, Baughman et al did not report any significant improvement with Etanercept therapy. (Baughman, Lower et al. 2005). Paradoxically, there are case reports on the development of sarcoidosis in RA during etanercept treatment. The pathogenesis for this is unclear. Mediastinal or pulmonary symptoms typically resolve after withdrawal of etanercept therapy. (Thongpooswan and Abrudescu 2014)

2.9.8.3 Adalimumab

There have been reports of improvement with adalimumab therapy in extra pulmonary sarcoidosis in case reports and small case series (Patel 2009, Field, Regan et al. 2010, Milman, Graudal et al. 2012). Pariser et al demonstrated effective and relatively safe treatment of adalimumab in a randomized controlled trial in cutaneous sarcoidosis (Pariser, Paul et al. 2013).

2.9.8.4 Other

Judson et al evaluated ustekinumab (anti-IL-12/23) or golimumab (anti-TNF α) treatment in a randomized placebo-controlled trial in chronic pulmonary and/or skin sarcoidosis. There was no significant difference in primary or secondary end points compared to placebo. (Judson, Baughman et al. 2014). Rituximab has been used in refractory pulmonary disease with inconsistent response (Sweiss, Lower et al. 2014). Of a series of four patients with refractory sarcoid granulomatous eye disease, three had clinical improvement with rituximab (Lower, Baughman et al. 2012). Positive individual case reports exist of rituximab use in cardiac and neurological sarcoid. (Bomprezzi, Pati et al. 2010, Krause, Cooper et al. 2016)

SUMMARY POINTS

- Sarcoidosis is a multisystemic inflammatory disorder characterised by the presence of epithelioid non-caseating granulomata in affected organs.
- It has a worldwide distribution and is slightly more common in women than in men. Prevalence peaks between 20 and 40 years of age and in women over 50. Studies on sarcoidosis show significant heterogeneity in incidence, prevalence, disease presentation and severity among different ethnic racial groups.
- The aetiology of sarcoidosis remains unknown, but several infectious agents and genetic factors have been implicated.
- Pulmonary involvement is present in 90% of cases with sarcoidosis, and up to 30% of patients present with extra pulmonary disease, including musculoskeletal, dermatological, ocular, cardiovascular, neurological and renal manifestations.
- Pulmonary involvement in sarcoidosis may range from radiographic stage I disease with bilateral hilar adenopathy without parenchymal involvement, to stage III or IV disease with pulmonary fibrosis, lung insufficiency and/or cor pulmonale.
- Musculoskeletal manifestations in sarcoidosis include acute arthritis, Lofgren's syndrome, chronic arthritis, tenosynovitis, myopathy and bone involvement.
- Lofgren's syndrome is characterised by hilar adenopathy, acute arthritis/arthralgias (ankle involvement is typical), and erythema nodosum. Lofgren's syndrome is usually self-limiting and has a good prognosis, usually requiring treatment with non-steroidal anti-inflammatory drugs only.
- A variety of non-specific laboratory abnormalities may be seen in patients with sarcoidosis. Sarcoidosis has been associated with hypercalciuria, hypercalcaemia and elevations in serum angiotensin-converting enzyme levels.
- Pulmonary imaging may reveal different stages of pulmonary sarcoidosis. Joint and bone radiographs may show non-specific radiographic changes.
- There are no specific diagnostic tests for sarcoidosis. The diagnosis rests on a combination of compatible clinical and radiographic manifestations, histological proof of non-caseating granulomata and exclusion of other diseases with similar presentation.
- Histological proof is not required in patients presenting with classic Lofgren's syndrome, but for all other patients with suspected sarcoidosis, biopsy is usually needed to confirm the diagnosis.
- Sarcoidosis is often a benign disease with good prognosis, unless there is cardiac and neurological involvement. Spontaneous remission occurs in 60–70% of cases, even more frequently in Lofgren's syndrome, and relapses are uncommon. Mortality is <5% and mainly results from respiratory failure related to pulmonary fibrosis, and refractory neurological or cardiac involvement.
- Glucocorticoids have been the most commonly used agents for the treatment of pulmonary and extra pulmonary sarcoidosis. Experience with other drugs is limited.

3. Palindromic rheumatism

LEARNING OUTCOMES

- Describe the clinical manifestations of palindromic rheumatism in terms of its episodic character, type, severity, duration of symptoms and distribution of joints involved
- Describe and evaluate laboratory and radiographic findings in palindromic rheumatism
- Describe the differential diagnosis of palindromic rheumatism
- Describe the clinical course of palindromic rheumatism by its disease patterns
- Describe and evaluate prognostic factors for the development of rheumatoid arthritis or other rheumatic diseases in patients with palindromic rheumatism
- Describe treatment options in palindromic rheumatism, and evaluate their level of evidence, efficacy and side effects
- Discuss the argument as to whether palindromic rheumatism should be viewed as a distinct clinical entity, or as a variant mode of onset of rheumatoid arthritis

3.1 Introduction

Palindromic rheumatism is a clinical entity originally described by Philip Showalter Hench and Edward Frank Rosenberg in 1944 (Hench and Rosenberg 1944). They described in great clinical detail and with many years of follow-up, 34 patients with a new distinct clinical entity, which they named 'palindromic rheumatism'. The condition is termed 'palindromic' because the rise in severity of symptoms and signs before reaching their maximum is mirrored by the subsequent decline in symptoms and signs back to normality. (A palindrome is a word, phrase or number that reads the same forwards as backwards, such as 'Amor Roma')

Palindromic rheumatism is characterized by multiple, recurrent, transient, episodes of acute arthritis and periarticular inflammation (associated tissue swelling around affected joints). Episodes last for a few hours to several days and then spontaneously resolve. Between acute inflammatory episodes there are no residual joint manifestations.

Although first described more than 60 years ago not much is known about palindromic rheumatism. Fifteen years after its initial description, the condition was revisited by Barbara Ansell and Eric Bywaters (Ansell 1959). They concluded that palindromic rheumatism is a variant or a mode of presentation of rheumatoid arthritis (RA). The majority of cases from their series of 28 patients with palindromic rheumatism eventually developed RA. The literature so far identifies a third to a half of all cases of palindromic rheumatism evolving into RA. However no clinical, immunologic, or genetic factor to predict who would develop RA has been identified. The question still remains whether palindromic rheumatism is a separate clinical entity or whether it should be considered a variant mode of onset of RA (Guerne and Weisman 1992).

3.2 Epidemiology

The prevalence of palindromic rheumatism in the general population is difficult to establish. It appears to be an extremely rare disease, although significant misclassification (as RA) cannot be ruled out. The prevalence is estimated to be one twentieth to one eighth that of RA (Pasero and Barbieri 1986, Guerne and Weisman 1992). The original description of palindromic arthritis did not find a clear female predominance. However, a recent cohort has identified 65% of cases were female, which is more in keeping with the sex distribution of RA (Gonzalez-Lopez, Gamez-Nava et al. 1999). The mean age of onset of palindromic rheumatism is about 45 years, but may vary from 20 to 80 years (Guerne and Weisman 1992). There is no known ethnic predisposition.

3.3 Pathogenesis

Pathogenesis of this disease is unknown.

3.3.1 Histopathological findings

Few histopathological studies have been performed in palindromic rheumatism, and histological findings are non-specific (Hench and Rosenberg 1944, Schumacher 1982, Guerne and Weisman 1992). Tissues obtained during an arthritic episode demonstrate periarticular oedema with gross thickening of the joint capsule and infiltration of large numbers of polymorphonuclear leucocytes. Similar changes were also noted in tendon sheaths. In between episodes, histological examination of joint and tendon tissues showed no significant inflammation. No pannus formation or cartilage destruction was found (Hench and Rosenberg 1944, Schumacher 1982, Guerne and Weisman 1992).

3.3.2 Genetics

Several studies have examined possible associations between HLA gene susceptibility and palindromic rheumatism to establish whether patients with palindromic rheumatism and patients with RA share the same immunogenetic characteristics.

The association of RA with MHC class II antigens is clearly established. Several studies have examined the role of HLA genes in predisposition to palindromic rheumatism and progression to RA. Some, but not all have reported associations with HLA-DR4. One study found similar HLA-DR4 frequencies in patients with RA and palindromic rheumatism; HLA-DR4 prevalence was 36.6% in controls, as compared with 60% in patients with palindromic rheumatism ($p < 0.05$) and 70% in patients with RA ($p < 0.005$) (Fisher, Kirk et al. 1986). However, other studies have found no clear associations (Gran, Husby et al. 1984). There is a report of two brothers with palindromic rheumatism sharing the HLA-DR4 and followed for 12 years, with arthritis remaining palindromic in the first brother, whilst the second developed chronic deformities and classical RA early in the course of the disease (Hannonen, Hakola et al. 1985). Bregeon et al demonstrated HLA-DR4 prevalence of 30.3% in controls, 31.2% in patients with palindromic rheumatism and 36% in patients with palindromic rheumatism who would later evolve to RA (Bregeon, Dajon et al. 1986).

In another series of 147 patients with palindromic rheumatism, the frequencies of HLA-DRB1 alleles were compared with those in 149 patients with RA and 149 controls (Maksymowych, Suarez-Almazor et al. 2002). The prevalence of the shared epitope was 39% in controls versus 65% in palindromic rheumatism (odds ratio 2.9, $p < 0.001$) and 77% in RA (odds ratio 5.1, $p < 0.001$). This was due to an increased prevalence of the DR1-0401 and 0404 alleles, but not DRB1-01.

Based on these similar immunogenetic risk profile, palindromic rheumatism may be considered as a continuous entity in which genetic factors influence the risk of progression from palindromic rheumatism to RA.

3.4 Clinical manifestations

3.4.1 Short-lived attacks of arthritis

The main distinctive feature of palindromic rheumatism is multiple, recurrent, transient, afebrile episodes of acute arthritis and periarticular disease. The episodes have a very sudden onset without any obvious inciting event. Symptoms progressively intensify with a peak within several hours. In most cases the episodes last for ≤ 48 h, sometimes for as little as 2h, and then spontaneously resolve (Guerne and Weisman 1992). Between arthritic episodes there are no residual articular effects, and patients are free of symptoms. The frequency of episodes is highly variable, ranging from one attack every other month to almost daily attacks (Hannonen, Mottonen et al. 1987). Patients with a high frequency of episodes may be more likely to develop RA (Bregeon, Dajon et al. 1986)

3.4.2 Joint distribution

Palindromic rheumatism attacks are typically monoarticular, although in rare cases several joints may be affected simultaneously. Different joints can be affected with each ensuing episode. Attacks are often excruciatingly painful and temporarily debilitating. Any may be affected, although palindromic rheumatism predominantly involves the wrists and the metacarpophalangeal and the proximal interphalangeal joints of the hands, followed by the knees, shoulders and ankles (table 1) (Mattingly 1966, Hannonen, Mottonen et al. 1987, Guerne and Weisman 1992, Emad, Anbar et al. 2014). One series suggests the involvement of hand joints is a clinical predictor of progression into RA within a year (Emad, Anbar et al. 2014). The spine and the jaw are rarely affected. When the spine is involved, it is usually at the cervical level (Guerne and Weisman 1992).

Table 1 Distribution of joints involved in episodes of palindromic rheumatism. (Adapted from Guerne and Weisman, *Am J Med* 1992;93:451–60)

Joint	% Of patients (mean)	% Of patients (range)
MCP/PIP	91	34.4–100
Wrists	78	5–82
Knees	64	10–94
Shoulders	65	5.5–75
Ankles	50	10–67
Feet	43	15–73
Elbows	38	13–60
Hips	17	0–40
Jaw	8	0–28
Spine	4	0–11
Sternoclavicular	2	0–6

MCP, metacarpophalangeal; PIP, proximal interphalangeal.

3.4.3 Periarticular inflammation

In one-third of patients, a characteristic periarticular or para-articular inflammation with marked redness is seen, especially when attacks involve the hands or the wrists. It resolves in a few hours or days (Guerne and Weisman 1992).

3.4.4 Transient nodules

A concomitant appearance of transient nodules during episodes of arthritis has been described. They are usually symmetrical and occur on the extensor surfaces of the hands. The nodules are smaller than those commonly seen in RA, and lack the typical histological features seen in rheumatoid nodules (Hench and Rosenberg 1944, Mattingly 1966, Guerne and Weisman 1992)

3.4.5 Other rare symptoms

Patients with palindromic rheumatism rarely present with constitutional symptoms, such as fever or weight loss, or with morning stiffness. Patients with these constitutional symptoms may be more likely to develop RA (Hannonen, Mottonen et al. 1987).

3.5 Laboratory findings

3.5.1 General

The erythrocyte sedimentation rate and the C-reactive protein are often mildly to moderately elevated during episodes of acute arthritis. In between episodes the acute phase reactants are usually not raised (Hench and Rosenberg 1944, Guerne and Weisman 1992). White blood counts and biochemistry studies are usually normal throughout the course of the disease. Transient anaemia was reported in a few patients (Mattingly 1966). Other investigations should be performed to exclude important differential diagnoses including uric acid, viral screen and Lyme serology.

3.5.2 Rheumatoid factor

Rheumatoid factor (RF) is found in serum samples of 30–60% of patients with palindromic rheumatism, according to different series (Wajed, Brown et al. 1977, Hannonen, Mottonen et al. 1987, Guerne and Weisman 1992, Russell, Devani et al. 2006, Emad, Anbar et al. 2014). Its presence has been associated both with greater severity of palindromic rheumatism and with a higher probability of developing RA during follow-up (Wajed, Brown et al. 1977, Bregeon, Dajon et al. 1986, Hannonen, Mottonen et al. 1987)(table 2).

Table 2 Percentages of RF-positive patients; among those who remained palindromic (PR–PR) during follow-up, and those who developed rheumatoid arthritis (PR–RA). (Adapted from Guerne and Weisman)

Reference	PR–PR (%)	PR–RA (%)	Follow-up (years)
Hannonen <i>et al</i> , 1987	11/25 (44%)	29/35 (83%)	5
Bregeon <i>et al</i> , 1986	3/16 (19%)	16/25 (64%)	10
Wajed <i>et al</i> , 1977	2/22 (9%)	16/17 (94%)	10

PR, palindromic rheumatism; RA, rheumatoid arthritis; RF, rheumatoid factor.

In one study, 29/35 (83%) patients with palindromic rheumatism who eventually developed RA were RF positive, compared with 11/25 (44%) patients who remained palindromic during follow-up. (Hannonen, Mottonen et al. 1987)

Seroconversion from RF negative to positive occurs in about 33% of seronegative patients with palindromic rheumatism, almost always shortly before they develop chronic arthritis. The percentage of RF-positive patients among those who remain palindromic is still higher than in the general population (Guerne and Weisman 1992).

3.5.3 Anti-cyclic citrullinated peptide

High frequencies of anti-cyclic citrullinated peptide (anti-CCP) antibodies have been found in serum samples of about half of patients with palindromic rheumatism (Salvador, Gomez et al. 2003, Russell, Devani et al. 2006, Emad, Anbar et al. 2014).

In one study the prevalence of anti-CCP antibodies was found in 56.3% of patients with palindromic rheumatism, 55% in the RA group and 2.5% in the spondyloarthropathy group (Salvador, Gomez et al. 2003). The presence of RF with anti-CCP antibodies was highly correlated in patients with palindromic rheumatism; a positive RF was found in 55.6% patients with anti-CCP antibodies and in only 21.4% patients without anti-CCP antibodies (Salvador, Gomez et al. 2003).

In another study of 61 patients with palindromic rheumatism 51% were RF positive and 56% were anti-CCP positive. Of these patients, 48% developed RA after a mean follow-up of 5.4 years (range 1–14 years) (Russell, Devani et al. 2006). Among those that developed RA, 83% were anti-CCP positive at presentation and 66% were RF positive. Three patients developed other rheumatic diseases (SLE, Behçet's disease, psoriatic arthritis). All three did not have anti-CCP (Russell, Devani et al. 2006). In another study of 90 patients with palindromic rheumatism the involvement of hand joints and positive anti-CCP were the only predictors that determined progression into RA within a year ($p < 0.001$ and $p = 0.02$, respectively) (Emad, Anbar et al. 2014).

However, a significant proportion of patients with palindromic rheumatism do not evolve to RA, even those with high titers of ACPA and a long follow up period. A recent study of 71 patients with palindromic rheumatism followed up for 7.6 ± 4.7 years found RA was more frequently seen in ACPA-positive than in ACPA-negative patients but the difference was not significant (Sanmarti, Cabrera-Villalba et al. 2012).

The results of these studies support the suggestion that palindromic rheumatism is a variant mode of onset of RA, and that anti-CCP antibodies, and RF, may be useful for predicting outcome.

3.5.4 Antinuclear antibodies

Antinuclear antibody studies are usually negative in palindromic rheumatism (Guerne and Weisman 1992). Complement levels are normal.

3.5.5 Synovial fluid analysis

Studies which carry out synovial fluid analyses are rare in palindromic rheumatism. Synovial fluid analysis may show variable cell counts (with up to 12 700 leucocytes/mm³), with variable differentials (2–66% polymorphonuclear cells)(Schumacher 1982). These findings do not correlate with the severity of the episodes (Guerne and Weisman 1992).

3.6 Radiographic findings

Radiographs are always normal in palindromic rheumatism. Erosions, joint space narrowing and periarticular osteopenia are absent(Hench and Rosenberg 1944, Guerne and Weisman 1992). Patients with palindromic rheumatism who progress to RA may develop erosions, with radiographic findings that are the same as those seen in classic RA) (Guerne and Weisman 1992).

Synovitis of wrists and small joints of the hands is detectable by ultrasound during the attacks in 36% of patients and more commonly in the presence of RF or anti-CCP antibodies (30% vs 5.6% and 26.7% vs 5.6%) (Chen, Lan et al. 2009) In the intercritical period most patients with palindromic rheumatism do not have US evidence subclinical synovitis, even those who are ACPA-positive.(Sanmarti, Cabrera-Villalba et al. 2012)

3.7 Diagnostic criteria

Several diagnostic criteria have been proposed for palindromic rheumatism, but none have been adopted by the American College of Rheumatology (Pasero and Barbieri 1986, Hannonen, Mottonen et al. 1987). One proposed set requires five criteria for the diagnosis of palindromic rheumatism (Pasero and Barbieri 1986)

1. 6-month history of brief, sudden-onset and recurrent episodes of monoarthritis or polyarthritis;
2. Direct observation of at least one attack by a physician;
3. Involvement of three or more joints, although they may be affected at different times;
4. Absence of erosions on radiographs;
5. Exclusion of all other arthritides.

Negative RF or anti-CCP antibodies do not seem to be an adequate diagnostic criterion, since a high prevalence of these antibodies is found in all palindromic rheumatism series, even in those patients who do not develop RA (Pasero and Barbieri 1986, Sanmarti, Cabrera-Villalba et al. 2012)

3.8 Differential diagnosis

In establishing the diagnosis of palindromic rheumatism, other forms of recurrent arthritis must be excluded. These include; crystal arthropathy, the most common cause of recurrent arthritis and several systemic diseases that may present clinically as intermittent monoarthritis or polyarthritis, such as reactive arthritis, systemic auto-inflammatory disorders (periodic fever syndromes) or Whipple's disease (Box 1) (Emad, Anbar et al. 2014).

Box 1 Diseases associated with recurrent attacks of arthritis (differential diagnosis of palindromic rheumatism)

- Crystal arthritis (gout, chondrocalcinosis, hydroxyapatite arthritis)
- Reactive arthritis
- Arthritis associated with inflammatory bowel disease (Crohn's disease, ulcerative colitis)
- Infectious arthritis (Whipple's disease, Lyme's disease, B and C hepatitis)
- Systemic autoinflammatory disorders (familial Mediterranean fever, TRAPS syndrome, hyper-IgD syndrome)
- Familial hyperlipidaemia
- Intermittent hydrarthrosis
- Sarcoidosis
- Vasculitis (ANCA vasculitis, cryoglobulinaemia, Behçet's disease, relapsing polychondritis)

TRAPS, tumour necrosis factor receptor associated periodic syndrome.

3.9 Course

In the natural history of palindromic rheumatism, three patterns of disease evolution have emerged (Guerne and Weisman 1992)

- Clinical remission of the attacks;
- Recurrent attacks, without persistent joint involvement;
- Progression to a chronic disease, which in most cases (93%) is RA

The RA which develops follows a similar course and has a similar severity to that of typical RA (Mattingly 1966, Williams, Sheldon et al. 1971, Wajed, Brown et al. 1977, Bregeon, Dajon et al. 1986, Hannonen, Mottonen et al. 1987, Guerne and Weisman 1992, Gonzalez-Lopez, Gamez-Nava et al. 1999, Koskinen, Hannonen et al. 2009, Emad, Anbar et al. 2014). The interval between the onset of palindromic rheumatism and the development of RA may vary from a few weeks to >20 years (Hannonen, Mottonen et al. 1987, Guerne and Weisman 1992). Emad et al study of 90 patients with palindromic rheumatism identified 27.5% progressed to RA at 1 year of follow-up (Emad, Anbar et al. 2014).

Other disorders that may rarely develop in patients with palindromic rheumatism include SLE (Russell, Devani et al. 2006, Koskinen, Hannonen et al. 2009, Emad, Anbar et al. 2014) and, anecdotally, spondyloarthropathies, psoriatic arthritis, Behçet's disease (Koskinen, Hannonen et al. 2009) or granulomatosis with polyangiitis (formerly Wegener's granulomatosis) (Gonzalez-Lopez, Gamez-Nava et al. 1999).

Nevertheless, significant numbers of patients with palindromic rheumatism do not change at all (about 50%), or enter into prolonged remission or are cured (about 15%). However, rates of remission and cure vary between studies, and may reflect heterogeneities between study populations and differences in criteria for remission and cure (Guerne and Weisman 1992)

3.10 Prognosis

Prognosis is generally good except in patients who progress to a chronic disease; the prognosis is then, that of the chronic disease (more often RA).

3.11 Treatment

No randomised, controlled trials have investigated drug treatment in palindromic rheumatism. Owing to of the relationship between palindromic rheumatism and RA, several drugs commonly used in RA have also been tried in palindromic rheumatism, including NSAIDs, antimalarial agents, gold salts, penicillamine and sulfasalazine. However, all subsequent reports on drug efficacy were from open, non-controlled clinical trials with a relatively small sample size. Therefore, conclusions on the true efficacy of these drugs in palindromic rheumatism should be considered with caution (Sanmarti, Canete et al. 2004).

3.11.1 Non-steroidal anti-inflammatory drugs

Treatment with NSAIDs may be effective in acute attacks, providing partial relief of joint pain in some patients. However they do not shorten the duration of attacks and rarely induce long-term remission. In two series of patients with palindromic rheumatism, treatment with NSAIDs appeared effective in about 68% of patients (Grattan, Kennedy et al. 1984, Eliakim, Neumann et al. 1989). However, in another clinical survey, only two out of 60 patients with palindromic rheumatism responded to NSAID treatment (Hannonen, Mottonen et al. 1987). Oral glucocorticoids are often used, but their effectiveness has not been demonstrated.

3.11.2 Antimalarial agents

Response rates with antimalarial agents vary between 15% and 80% in different studies. High response rates were found in a series of 51 patients with palindromic rheumatism; 80% patients experienced marked

improvement, with a reduction of the intensity or frequency of attacks. Nevertheless, 23% of the patients eventually developed RA, despite use of chloroquine (Youssef, Yan et al. 1991). In another series of 90 patients, 43 responded to hydroxychloroquine with complete remission (Emad, Anbar et al. 2014)

In a retrospective study of 113 patients with palindromic rheumatism from the same institution, the use of antimalarial drugs was associated with a reduced risk for the development of RA (Huskisson 1976). Although the proportions of treated (24%) and untreated (35%) patients who finally developed RA were not significantly different, the estimated time to development of chronic arthritis was a median of 162 months in those treated with antimalarials and a median of 56 months in untreated patients. This study thus suggests a possible role for antimalarial agents in preventing or delaying the development of RA in patients with palindromic rheumatism (Huskisson, 1976).

3.11.3 Other disease-modifying antirheumatic drugs

Surprisingly, there is little or nothing in the literature about the use of methotrexate, leflunomide or anti-TNF- α , or glucocorticoids in palindromic rheumatism.

Sulfasalazine has also been found to be effective, with a favourable response in about 50% of patients (Hannonen, Mottonen et al. 1987, Golding 1988).

Gold salts were widely used in the treatment of palindromic rheumatism, although their use has gone out of fashion. Response was noted in up to 66% of patients treated with injectable gold, often after only a few weeks of treatment (Mattingly 1966, Hannonen, Mottonen et al. 1987, Eliakim, Neumann et al. 1989) However, one of these series reported high numbers of cutaneous side effects (Mattingly 1966). In another series of patients with palindromic rheumatism, gold treatment was associated with disease remission in only 20% of the patients, while spontaneous remission occurred in 42% of untreated patients (Bregeon, Dajon et al. 1986).

Penicillamine seemed to be very effective in one case series, inducing complete remission in four out of five patients with palindromic rheumatism (Huskisson 1976). Other case series did not show such good responses (Bregeon, Dajon et al. 1986, Hannonen, Mottonen et al. 1987)

Colchicine has been used for the treatment palindromic rheumatism due to the similarity with familial Mediterranean fever. In a small series of five patients, a dose of 0.6 mg twice daily achieved good results in all five patients (Schwartzberg 1982).

3.12 RA or not RA

Arguments for considering palindromic rheumatism a variant mode of onset of RA include:

- Up to 50% of patients with palindromic rheumatism develop RA.
- High prevalence of the shared epitope in palindromic rheumatism.
- High prevalence (about 50%) of patients with RF and anti-CCP in palindromic rheumatism.
- Presence of subcutaneous nodules, albeit usually with dissimilar histopathology.
- There is some response to common treatments of RA, however, the responses are variable and not as effective as in RA.

Arguments for considering palindromic rheumatism as a distinct clinical entity:

- Different epidemiology and demographics
- No strong HLA-DR4 association.
- Different disease pattern, with recurrent episodes of acute arthritis separated by asymptomatic intervals.
- No constitutional symptoms, no morning stiffness.
- Different histopathology, no pannus formation, no erosions, no bone or joint destruction.

SUMMARY POINTS

- **Palindromic rheumatism is characterised by recurrent transient episodes of acute arthritis and periartthritis. Episodes last for a few hours to several days and then spontaneously resolve, with symptom-free periods that may last from days to months.**
- **Attacks are typically monoarticular, affecting the hands, wrists, knees, shoulders and ankles. Transient subcutaneous nodules may be seen.**
- **Palindromic rheumatism affects men and women equally.**
- **Several diseases should be ruled out in the differential diagnosis, especially crystal arthritis.**
- **Imaging studies in palindromic rheumatism show no pannus formation, no erosions and no bone or joint destruction.**
- **There is a high prevalence of rheumatoid factor (RF) and anti-cyclic citrullinated peptides (anti-CCP) in palindromic rheumatism.**
- **Three patterns of disease evolution may be seen in palindromic rheumatism: clinical remission of the attacks in 15%, clinical course of recurrent attacks without persistent joint involvement in 35%, evolution, predominantly to rheumatoid arthritis, in 50%.**
- **Risk factors for the evolution of palindromic rheumatism to rheumatoid arthritis appear to be RF and/or anti-CCP antibodies positivity, female sex and involvement of the hands.**

IN-DEPTH DISCUSSION I

Paraneoplastic rheumatic conditions

Introduction

Paraneoplastic syndromes are collections of disorders that are the indirect result of a tumour or its metastases. They are mediated by hormones and cytokines from a tumour, or a consequence of humoral or cellular immune defence mechanism against tumour cells cross-reacting with normal tissues at regions distant from the underlying malignancy. Paraneoplastic syndromes in rheumatology are rare. However, causative malignancies are often non-metastatic and thus potentially curable.

Musculoskeletal symptoms arise in joints, fasciae, muscles, vessels or bones, and generally present generally no longer than 2 years before the diagnosis of an associated neoplasm. Rheumatologists should be aware that signs and symptoms compatible with a benign rheumatic condition might be caused by malignancies. Signs and symptoms not fitting the clinical pattern of the simulated rheumatic condition often provides diagnostic clues.

Rheumatological manifestations of paraneoplastic conditions

Hypertrophic osteoarthropathy

Hypertrophic osteoarthropathy (HOA) may be seen in lung cancers and pleural mesothelioma. Tibial and femoral bone pain is the typical musculoskeletal symptom, and arthralgia or synovitis of adjacent joints is common. On X-ray, typical elevation (thickening and detachment) of the periosteum may be present and the formation of new osseous tissue leads to increased tracer uptake on bone scans or PET (figure 1).

Digital clubbing is another characteristic finding of HOA (figure 1). It presents with periungual erythema and hyperextensibility of the distal interphalangeal joints. A lesser-known clinical sign found in association with HOA in cancer is acanthosis palmaris (also known as tripe palms), a hyperkeratotic accentuation of dermatoglyphic lines, which gives the palmar skin a gyrated, velvety appearance. (Manger and Schett 2014)

With treatment of lung cancer, around 50% have improvements in symptom and bone scintigraphy. Periostitis and bone pain respond well to NSAIDs, and zoledronic acid have also been used successfully. (Jayakar, Abelson et al. 2011)

HOA may develop in the absence of malignancy. Indeed, the original description of clubbing has been attributed to Hippocrates in the setting of chronic empyema. Any chronic suppurative lung or gastrointestinal disease (e.g. cystic fibrosis or Crohn's disease) can cause digital clubbing. The postulated mechanism of the disease relates to excess prostaglandin E₂ production. An inherited pattern HOA is also described, with a

typical onset during teenage years – and inherited in an autosomal dominant manner. Mutations in genes encoding prostaglandins (e.g. *SLCO2A1*) have been identified (Zhang, Xia et al. 2012).

Other paraneoplastic bone disease includes tumour-induced osteomalacia and hypercalcemia of malignancy.

Figure 1 A patient with clubbing of the fingers and toes. A bone scan disclosed periostosis in the wrists as a paraneoplastic syndrome (hypertrophic osteoarthropathy).

Paraneoplastic polyarthritis

The coexistence of polyarthritis and cancers does not indicate a causal relationship, unless there is a close temporal association or treatment of the tumour leads to remission of joint symptoms (Naschitz and Rosner 2008). The history is typically of an explosive onset, migratory or additive non erosive asymmetric polyarthritis. It can be accompanied by constitutional symptoms and elevated markers of inflammation (Racanelli, Prete et al. 2008). Response to corticosteroids and disease-modifying antirheumatic drugs is typically poor.

Paraneoplastic polyarthritis arise from haematologic malignancy in one third of cases. The most common haematological diagnosis is myelodysplastic syndrome, and the pattern of polyarthritis is typically that of a seronegative rheumatoid. Polyarthritis is also occasionally observed in the setting of solid tumours such as adenocarcinomas of the lung and breast. Carcinoma of the pancreas may present as arthritis of the large lower limb joints, accompanied by erythema nodosum-like lesions. (Manger and Schett 2014).

Remitting seronegative symmetrical synovitis with pitting oedema (RS3PE)

RS3PE is a symmetrical polyarthritis involving the small joints with marked pitting oedema on the dorsum of the hands and feet. It characteristically seen in elderly people, and has a sudden inflammatory onset. In 5 small case series, with a total of 89 patients with RS3PE, malignancy was reported in 22 patients (24.7%). (Sibilia, Friess et al. 1999, Paira, Graf et al. 2002, Russell 2005, Manger and Schett 2014).

Whilst idiopathic and paraneoplastic RS3PE are similar demographically and clinically, idiopathic disease demonstrates a rapid response to corticosteroid therapy, whilst response may be diminished or delayed in paraneoplastic disease.

Polymyalgia Rheumatica (PMR)

Polymyalgia rheumatica is a relatively common disease in the elderly. Its association with cancer is controversial but an atypical picture; age <50 year, limited or asymmetrical involvement of typical sites, poor or incomplete response to low doses of glucocorticoids should suggest this possibility. Myelodysplastic syndromes and myeloproliferative syndromes are malignancies associated with PMR.

Palmar fasciitis and polyarthritis syndrome (PFPAS)

Palmar fasciitis and polyarthritis also known as palmar fibromatosis is a rare disorder described in association variety of malignant neoplasms, most commonly ovarian cancer.

It presents with erythema and thickening of the palmar fascia with the development of firm, painful nodules. This is associated with digital swelling and flexion contractures, reminiscent of Dupuytren's contracture but more widespread. Polyarthritis may sometimes accompany the fibrosis. (Azar and Khasnis 2013)

Amyloid arthropathy

Amyloid arthropathy is very rarely seen in myeloma, renal carcinoma and lymphoma. Amyloid can deposit in the synovium leading to rheumatic symptoms, most commonly at the shoulders, knees, wrists, and metacarpophalangeal and proximal interphalangeal joints. Other findings include subcutaneous nodules, similar to rheumatoid nodules, carpal tunnel syndrome and macroglossia. Congo red staining of synovial sediment demonstrates amyloid deposits.

Cancer-associated myositis

About 13–42% of patients with dermatomyositis (DM) (figure 2) and 3–18% of patients with polymyositis have associated malignancy. The leading malignancies in DM are ovarian and breast cancer in women, and lung cancer in men. These may be present in patients either before, after or during diagnosis of myositis.

The clinical picture in patients with cancer associated myositis is often severe muscle and cutaneous involvement. Skin ulceration may occur. Interstitial lung disease is less common.

Anti-NXP-2 and anti-155/140 antibodies targeting transcription intermediary factor 1 (TIF-1) family proteins (particularly, TIF-1γ) are often found in DM (55% of patients) and are present in most patients with cancer-associated DM (Chinoy, Fertig et al. 2007, Fiorentino, Chung et al. 2013). The presence of myositis-specific

(anti-synthetase antibodies, anti-Mi-2, anti-SRP) and myositis-associated antibodies (anti-RNP, anti-PM-Scl, anti-Ku) make an underlying malignancy less likely.

Figure 2 Scaly, erythematous plaques located over the knuckles (Gottron's papule as a pathognomonic signs of dermatomyositis).

Connective tissue disorder symptoms

Raynaud's phenomenon and scleroderma-like syndrome may occasionally be a paraneoplastic. Asymmetric involvement of the fingers, rapidly evolving to necrosis with a poor response to vasodilator therapy and sympathectomy should arouse suspicion of paraneoplastic Raynaud's phenomenon. The absence of Raynaud's with a normal capillaroscopy pattern can be a distinguishing feature of cancer-induced systemic sclerosis. (Racanelli, Prete et al. 2008) Skin changes resembling scleroderma may also occur in patients with osteosclerotic myeloma (POEMS syndrome). The widespread form of scleroderma is found in malignancies of the breast, uterus and lung, whilst the localised form is seen in carcinoids and bronchoalveolar lung tumours. The association between lupus and malignancy is rare.

Vasculitis

The incidence of malignancies in patients with vasculitides has been estimated to be 8%. Cutaneous leucocytoclastic vasculitides is the most common paraneoplastic type, which has a high association with lymphoproliferative disorders and myelodysplastic syndromes; solid neoplasms are less common. Henoch Schönlein purpura (HSP) in adults has been described in association with solid tumours (Podjasek, Wetter et al. 2012). Relapsing polychondritis (RP) has been reported in association with myelodysplastic syndromes and haematological manifestations can precede, occur simultaneously or develop subsequently to RP (Van Besien, Tricot et al. 1992, Myers, Gould et al. 2000).

Chemotherapy-related musculoskeletal conditions

Aromatase inhibitors: Aromatase inhibitors used in the treatment of breast cancer are associated with arthralgia and subjective joint stiffness, occurring in 40-50%, which can result in discontinuation in 10% of patients (Henry, Giles et al. 2008). The musculoskeletal symptoms can persist for many months after withdrawal of therapy.

Bleomycin: Cases of scleroderma and Raynaud phenomenon have been noted in association with the use of bleomycin.

Taxanes: Taxanes, such as paclitaxel and docetaxel can cause myalgia and arthralgia that is sometimes severe. Taxanes can also photosensitive-distribution skin rashes which is similar clinically and histologically to subacute cutaneous lupus.

Other organ manifestations of paraneoplastic conditions

Gastrointestinal

Diarrhoea accompanied by an electrolyte imbalance may lead to weight loss, confusion and exhaustion. These problems are typical of patients with proctosigmoid tumours and of prostaglandins producing tumours like the medullary thyroid carcinomas.

Renal

Patients with tumours that secrete adrenocorticotrophic hormone (ACTH) or ACTH-like substances (Cushing's syndrome) may have hypokalaemic nephropathy, which is characterised by urinary potassium leakage of >20 mEq/24 h. This occurs in 50% of people with ACTH-secreting tumours of the lung (ie, small-cell lung cancer). Other hormones like antidiuretic hormone may cause hyponatraemia (frequent in small-cell cancer).

A nephrotic syndrome is seen, although seldom, in patients who have Hodgkin's lymphoma; non-Hodgkin's lymphoma; leukaemia; melanoma; or malignancies of lung, thyroid, colon, breast, ovary or pancreatic head. Patients with myeloma, renal carcinoma or lymphomas present rarely with secondary amyloidosis of the kidneys, heart or central nervous system.

Haematological

Erythrocytosis or anaemia, thrombocytosis, disseminated intravascular coagulation and leukaemoid reactions may result from many types of cancers. Thrombocytosis ($>500 \times 10^9/L$) leads to migrating thrombophlebitis that is resistant to standard anticoagulant therapy and affects the arm veins, the inferior vena cava and the

jugular veins. It usually appears as oval formations along the little and middle veins, accompanied by cutaneous necrosis and marantic (non-bacterial) endocarditis characterised by thrombotic growths developing on the heart valves that may break and form clots and emboli.

Leukaemoid reactions, characterised by the presence of immature white blood cells in the bloodstream, are usually accompanied by hypereosinophilia and itching. These reactions typically are seen in patients with lymphomas or cancers of the lung, breast or stomach.

Cutaneous signs and symptoms

It is well known that itching (pruritus) is the most common cutaneous manifestation in patients with cancer. Herpes zoster, ichthyosis (figure 3), flushes, alopecia (figure 4) or hypertrichosis may also be presenting symptoms of cancer. Acanthosis nigricans (figure 5) and dermic melanosis are characterised by a blackish pigmentation of the skin and usually occur in patients with metastatic melanoma, gastric tumour or pancreatic tumours.

Figure 3 Ichthyosis, which in the early stages could mimic a benign dermatosis, is characterised by desquamation of the extensory surface of the limbs (resembles the scales of a fish, in ancient Greek ichthys means fish). (Source: SKINmed. Copyright 2004, Le Jacq Communications Inc. <http://www.medscape.com>)

Figure 4 Localised alopecia due to metastatic renal cell cancer.

Figure 5 Acanthosis nigricans and dermic melanosis are often diagnostic clues for the presence of a malignancy. They are similar but differ in location. Dermic melanosis is diffuse; acanthosis nigricans usually is accompanied by confluent papillomas and affects the oral, umbilical, axillary and inguinal areas.

Endocrine signs and symptoms

Cushing's syndrome, accompanied by hypokalaemia, very high plasma ACTH levels and increased serum and urine cortisol concentrations, is the most common example of an endocrine disorder linked to a malignancy. This is related to the ectopic production of ACTH or ACTH-like molecules from many tumours (eg, small-cell cancer of the lung). The syndrome of inappropriate antidiuretic hormone hypersecretion is found in up to 15% of patients with small-cell lung cancer but may be related to other malignancy.

Neuromuscular signs and symptoms

Each part of the nervous system can be affected by a neoplastic condition.

- Sensory neuropathy, originates from ganglionic degeneration.
- Mixed neuropathy appears with several malignancies and has an extremely variable presentation.

- The spinal cord can be affected by either subacute necrotic myelitis or subacute myelitis. A lateral amyotrophic syndrome (LAS) may occur, presenting with typical muscular asthenia and atrophy, hyper-reflexia with pyramidal fasciculations and degeneration of the second motor neuron. This form of LAS differs from the non-paraneoplastic form because it includes sensory involvement (ie, proprioception and pallesthesia).
- The cerebellum may be the site of subacute neuronal degeneration in patients with small-cell carcinoma or breast or gynaecological tumours.
- An example of paraneoplastic neuromuscular disorder is the Eaton–Lambert myasthenic syndrome, which manifests as asthenia of the scapular and pelvic girdles and a reduction of tendon reflexes. It may occur in patients with lymphomas; thymomas; or cancers of the pancreas, rectum, kidney, breast, prostate or uterus.

Management

Patients suspected of having a paraneoplastic condition need a complete diagnostic work-up. This ought to be individualised and based upon the presenting features, the physical examination, the differential diagnosis and the most likely underlying cause. Also, one should take into account the curability of possible underlying conditions. Tailored laboratory investigations, sometimes including tumour markers, autoantibodies and imaging studies, should lead to histological evidence for the underlying neoplasm.

In many cases successful treatment of the malignancy will lead to reduction and disappearance of the paraneoplastic symptoms. When indicated symptomatic treatment of the rheumatic symptoms includes the prescription of non-steroidal anti-inflammatory drugs, glucocorticoids or immunosuppressive drugs. However, the curative treatment of the underlying neoplasm always has priority. The role of the rheumatologist as part of the team of physicians treating a patient with a paraneoplastic condition is most important in the diagnostic phase.

IN-DEPTH DISCUSSION II

Hypertrophic osteoarthropathy

Introduction:

Hypertrophic osteoarthropathy (HOA) is a clinical syndrome characterized by excessive proliferation of skin and bone tissue at the distal parts of the extremities (Martinez-Lavin et al. 1993). The triad of HOA includes new periosteal bone formation (periostosis) in the tibia, fibula, radius or phalanges, thickening of the skin, most notable on the scalp and forehead, and clubbing of the fingers (first described by Hippocrates 2500 years ago) (Figure 1 & 2).

There is a rare familial primary form, also known as pachydermoperiostosis. This is not associated with any other medical disorders. A secondary form of HOA is associated with primarily non-small cell lung cancer (Pierre Marie-Bamberger syndrome), chronic pulmonary conditions (hypertrophic pulmonary osteoarthropathy, HPOA), chronic cardiac conditions, such as right-to-left cardiac shunts, and less often with hepatic (liver cirrhosis) or intestinal disease (Box 1). Patients with HOA may have joint symptoms, ranging from mild to severe arthralgias that involve the metacarpal joints, wrists, elbows, knees and ankles, to arthritis of the larger joints.

Figure 1: Frontal and lateral radiographs of the distal femur showing a thick, wavy periosteal reaction that involves the diaphysis but spares the epiphysis

Figure 2: Clubbing of the finger, also known as 'drumstick fingers', 'Hippocratic fingers' and 'watch-glass nails'.

Box 1. Secondary causes of HOA

Childhood Secondary HOA	Adulthood Secondary HOA
Pulmonary infections, Cystic fibrosis, Congenital cyanotic heart disease, Osteosarcoma and lung metastasis	Intrathoracic infections or cancer (90%) <ul style="list-style-type: none"> - Non-small cell (squamous cell/ adenocarcinoma) - Metastatic lung disease, - Pleural mesothelioma, - Oesophageal carcinoma, - Hepatocellular carcinoma, - Rhabdomyosarcoma - Renal cell carcinoma Other <ul style="list-style-type: none"> - Pulmonary fibrosis - Infective endocarditis - Arteriovenous fistula - Liver (cirrhosis, primary sclerosing cholangitis) - GI (chronic infections, laxative abuse, polyposis, IBD) - Miscellaneous (thymoma, POEMS syndrome, thalassemia, myelofibrosis)

Epidemiology:

There have been no systematic studies into the incidence and prevalence of HOA. Primary or idiopathic HOA appears to be a very rare condition. Only 3-5% of patients with HOA have primary HOA. The remaining 95-97% have secondary HOA.

Primary HOA has a male-to-female ratio of 9:1 and shows a predilection for blacks. There is a bimodal peak of onset in the 1st year of life and around the 15th year. Primary HOA usually has a chronic course. The activity of the illness is limited to the growth period, with adults becoming asymptomatic and demonstrating a normal life expectancy (Box 2). Long-standing finger clubbing and a positive family history suggest primary HOA (Martinez-Lavin et al. 1988).

In secondary HOA, the incidence and prevalence, sex ratio and mortality and morbidity depend upon, and vary with the associated illnesses (Yao et al. 2009).

Box 2. Epidemiologic Features of HOA

Primary HOA	Secondary HOA
Male/female: 9/1	Epidemiology that of underlying condition
Clustering in families	Morbidity/ mortality in accordance with underlying condition
Predilection for blacks	
Peak incidence in 1 st and 15 th year of life	
Chronic course	
Active disease during childhood	
Asymptomatic in adulthood, normal life expectancy	

Aetiology:**Primary HOA:**

Primary HOA (pachydermoperiostosis or Touraine-Solente-Gole syndrome) is an autosomal dominant condition that presents in childhood and clinically resembles secondary HOA. The genetic abnormality is a mutation in the HPGD gene that encodes 15-hydroxyprostaglandin dehydrogenase, the primary enzyme responsible for prostaglandin degradation (Uppal et al. 2008). However this is not identified in all case and more recently other mutations in genes encoding a prostaglandin transporter protein (e.g. SLCO2A1) have been identified (Zhang et al. 2012). Homozygous individuals have persistently elevated prostaglandin E2 (PGE2) concentrations and clinical symptoms of HOA, while heterozygous individuals have less pronounced biochemical and clinical manifestations. Interestingly due to persistent high levels of PGE2, in the postnatal period, affected individuals are prone to persistent patent ductus arteriosus. Circulating PGE2 might also be pathophysiologically important in secondary HOA as increased serum prostaglandin concentrations have been demonstrated in some of the underlying conditions.

Secondary HOA:

The exact aetiology of secondary HOA is unknown. Paraneoplastic, neurologic, hormonal and immune mechanisms, as well as vascular thrombi caused by platelets and antiphospholipid antibodies have all been proposed as possible causes.

Paraneoplastic growth factor: vascular endothelial growth factor (VEGF)

This hypothesis involves a paraneoplastic growth factor produced by the tumour and released into the circulation. This growth factors promotes the pathological hallmark features of HOA; vascular proliferation, oedema and subperiosteal new bone formation (Martinez-Lavin et al. 2008). One candidate for such a factor is vascular endothelial growth factor (VEGF). VEGF is a platelet-derived factor induced by hypoxic environments. It is angiogenic, permeability-enhancing and a bone-forming agent. Diverse types of cancer produce VEGF as a

mechanism of tumour dissemination. Two case reports have independently noted an association between lung tumour production of VEGF and clinical signs of HOA (Abe et al. 2002, Olan et al. 2004).

Circulatory bypass of the lungs

This hypothesis involves the possible circulatory bypass of the lungs. Many illnesses associated with HOA involve alterations of lung function with significant intrapulmonary shunting of blood. In patients with patent ductus arteriosus complicated by pulmonary hypertension and a right-to-left shunt, HOA is evident only in the limbs that receive unsaturated blood. Furthermore, HOA can be induced in dogs by surgically producing right-to-left shunts.

Normally, megakaryocytes are fragmented in the pulmonary microvasculature before they reach the general circulation. Having escaped fragmentation through shunting, megakaryocytes reach the distal extremities where they may cause local endothelial cell activation through the release of growth factors, such as platelet-derived growth factor, transforming growth factor and VEGF. This may initiate finger clubbing by inducing connective-tissue matrix synthesis and new bone formation through VEGF receptors expressed in subperiosteal bone-forming cells (Dickinson 1993).

Clinical manifestations

Primary HOA

The clinical manifestations may vary. Onset is usually insidious, slowly progressing and essentially asymptomatic. Patients rarely voluntarily report symptoms of clubbing and skin manifestations. These manifestations progressively become part of the patient's body image and the patient usually considers them more or less normal. Homozygous individuals may have more pronounced symptoms than heterozygotes.

In its complete form primary HOA manifestations include pachydermia (abnormal thickening of the skin), periostitis and cutis verticis gyrata (convoluted folds and furrows from a thickened skin of the scalp resembling a cerebriform pattern) (Figure 3). In the incomplete form there may be sparing of the scalp or pachydermia with only minimal or absent periostitis. Further symptoms may include enlargement of the hands and feet, clubbing of the distal fingers and toes, ptosis, excessive sweating, fatigability, bone and joint pain, hepatosplenomegaly, anaemia, and endocrine abnormalities (Castori et al. 2005).

Secondary HOA

The history, course and development of clinical manifestations of secondary HOA depend on the underlying illness. Secondary HOA usually progresses faster than primary HOA. Patients with HOA secondary to lung

cancer may have acute onset of digital clubbing, with a red colour, heat and burning sensation of the fingertips, with sweating, clumsiness, and stiffness of the hands. In addition, pain and swelling in joints and long bones and occasionally thickening of the skin is described. In one series of 111 consecutive patients with pathologically proven lung cancer, clubbing was present in 29%. Clubbing was more common among women than men (40% versus 19%) and in non-small cell cancer compared to small cell lung cancer (35% versus 4%) (Sridhar et al. 1998). Other types of secondary HOA may have a more insidious onset of digital clubbing, skin thickening and arthritis.

Clubbing

Digital clubbing is common but not universal in HOA. It usually progresses through several phases.

1. fluctuating softening (sponginess) of the nail bed. Palpation of the nail produces a rocking sensation of the nail due to oedema and increased soft tissue underneath.
2. loss of the normal 15° angle between the nail bed and cuticle (Lovibond angle) on lateral view
3. accentuation of the convexity of the nails
4. progressively clubbed appearance of the fingertips, accompanied by warmth and sweating
5. there is a shiny or glossy change in the nail and adjacent skin, with disappearance of the normal creases and the appearance of longitudinal striation of the nail

Normally, when the distal interphalangeal (DIP) joints and the nail bed of the right and left index finger are placed in apposition, an oblong diamond-shaped aperture is visible between the 2 juxtaposed nail beds. With clubbing, this diamond-shaped space disappears. The mean ratio of the nail bed circumference to the DIP joint circumference should normally be less than 1. If the ratio is greater, clubbing is present. Clubbing may be symmetrical (all the fingers and/or toes), unilateral (one hand or foot) or unidigital (one finger or toe) (Hansen-Flaschen and Nordberg 1987). Localized clubbing has been associated with local neurological or vascular lesions such as aneurysms, arteriovenous fistulas, venous abnormalities and infected arterial grafts.

Periostosis

Periostosis is especially associated with malignancies. It occurs more often in the tubular bones of the lower extremities than in the upper limbs. Periostosis may be asymptomatic or may cause a severe burning and deep-seated pain in the distal extremities. The pain is aggravated with hanging of the limb and relieved with elevation. It is usually painful on palpation of the involved area. Most often involved are the tibia, fibula, radius, ulna, femur, humerus, clavicle, metacarpal, and metatarsal bones (Martinez-Lavin et al. 1988).

Joint symptoms

Joint symptoms are present in 30-40% of patients with HOA at some time during the course of the disease. Often these articular symptoms are the presenting manifestations. Pain and tenderness occur most often in the knees, ankles, wrists, elbows and metacarpophalangeal joints. These symptoms are usually more severe during the night and exacerbate with movement. The range of motion of affected joints may be decreased. Involvement of the joints is usually symmetric, with synovial effusions of especially the larger joints. Arthrocentesis reveals a viscous non-inflammatory synovial fluid, with a cell count of less than 500 cells/ μ L and few leukocytes and neutrophils. The effusions are more likely to be a sympathetic reaction to nearby periostosis than an inflammatory synovitis. Some patients present with a painful arthropathy months in advance of clubbing, constitutional- or respiratory symptoms, and the presentation may thus initially resemble other polyarticular conditions, like rheumatoid arthritis.

Cutaneous symptoms

Cutaneous symptoms are more prominent in primary than in secondary HOA. Hypertrophy of soft tissues may occur, resulting in coarse facial features, cylindrical calves (elephant feet), ptosis of the eyelids, and cutis verticis gyrata or prominent frontal or scalp cerebriform wrinkles. Additionally dysfunction of exocrine glands within the skin results in acne, hyperhidrosis or seborrhoea. (Martinez-Lavin et al. 1988, Gomez Rodriguez et al. 2009)

Figure 3: cutis verticis gyrata: thickened skin of the scalp resembling a cerebriform pattern.

Workup:

A bone scan is a sensitive way to detect which bones are involved. However, neither radiographic nor radionuclide findings are specific for HOA.

Plain radiographs

Plain radiographs may show 2 types of changes

- bone formation with hypertrophy
- bone dissolution with acro-osteolysis (figure 4).

Hypertrophy predominates in patients with HPOA secondary to lung cancer, whereas acro-osteolysis predominates in patients with HOA secondary to cyanotic congenital heart disease. The type of bone remodelling process depends on the age when clubbing develops. If clubbing appears in childhood, osteolysis is more prominent and if it develops after puberty, hypertrophic changes take place.

Periosteal bone deposition occurs along the shafts of long bones, initially appearing in the proximal and distal diaphyses of the tibiae, fibulae, radii, ulnae, and less frequently the femora, humeri, metacarpals, metatarsals, and phalanges (with exception of the terminal phalanges). Various types of periosteal changes are seen: simple elevation of the periosteum, seen as a continuous thin line of sclerotic new bone separated from the subjacent cortex by a radiolucent area; laminated or 'onion-skin' appearance, with smooth layers of new bone formation; irregular areas of periosteal elevation; cortical thickening (Pineda et al. 1990).

Over time, the appearance of the periostosis may change; the periosteal new bone thickens and fuses with the cortex, and the process extends proximally to the diaphysis and metaphysis. In primary HOA periosteal new bone formation may extend into the epiphyseal regions. Acro-osteolysis may be seen in the distal tufts in patients with long-standing HOA with clubbing.

Figure 4: radiograph of both hands in a 42 year old man with primary HOA with finger clubbing and acro-osteolysis of the terminal phalanges.

Radionuclide bone imaging

Radionuclide bone imaging is a highly sensitive method for detecting bone abnormalities in primary or secondary HOA. Radionuclide bone scanning using technetium Tc 99m polyphosphate shows increased uptake of the tracer in the periosteum, often appearing pericortical and linear as a 'double stripe' or parallel track' (figure 5). Scintigraphic abnormalities frequently appear well before the radiographic findings and correspond well with clinical findings. Associated synovitis and clubbed digits may also show increased uptake in early passage flow studies. Angiography findings may demonstrate hypervascularisation of the finger pads (Hansen-Flaschen and Nordberg 1987).

Figure 5: 99m Tc-MDP bone scintigraphy in HOA secondary to bronchial carcinoma, showing linear, subperiosteal increased uptake along shafts of long bones.

Chest X-ray

When HOA is suspected, a chest X-ray should be performed because the most frequent cause of acute onset of HOA is lung cancer.

Treatment:

The most effective treatment for secondary HOA is treatment of the underlying condition. Removal of the primary tumour or treatment of the other causes of HOA usually results in regression of the clinical manifestations. As early as 1976, Atkinson et al reported that chemotherapy treatment of Hodgkin Lymphoma,

also led to complete resolution of HOA symptoms (Atkinson et al. 1976). With treatment of lung cancer, around 50% have improvements in symptom and bone scintigraphy (Ito et al. 2010). Correction of cyanotic heart malformation is also effective in relieving HOA symptoms. Frand et al reported two cases of HOA-associated cyanotic heart disease corrected by surgery led to complete resolution of clinical and radiological signs of HOA (Frand et al. 1982).

Periostitis and bone pain respond to steroidal anti-inflammatory drugs (NSAIDs). This may be related to blocking of cyclo-oxygenase-2 (COX-2), an enzyme that is involved in the formation of prostaglandins (PGE). Kozak et al reported the use of rofecoxib in a 65-year-old woman with HOA secondary to metastatic non-small cell lung cancer. Her pain was refractory to high-dose narcotics, but completely resolved with rofecoxib, although clubbing did persist (Kozak et al. 2006).

Another promising treatment is reported with octreotide, a somatostatin analogue. Its role is well-established in controlling growth and secretions in acromegaly and neuroendocrine tumours. It is suggested that the analgesia effect in HOA may due to its inhibitory effect on the production of VEGF and endothelial proliferation. (Nguyen and Hojjati 2011)

Lastly, in patients with refractory disease, bisphosphonates including pamidronate and zoledronic acid which are potent inhibitor of osteoclastic bone resorption have been used successfully (Jayakar et al. 2011) (Amital et al. 2004) (King and Nelson 2008). It is unclear how bisphosphonates fit in the scheme of suggested HOA pathogenesis mechanism, however while the inhibitory effects of bisphosphonates on bone metabolism may be responsible for its benefits, both pamidronate and zoledronic acids have been shown to decrease levels of plasma VEGF in patients with cancer. (Nguyen and Hojjati 2011).

It therefore plausible that other agents that inhibit VEGF may be successful in the treatment of HOA. This is especially interesting with the more recent use of anti-VEGF antibodies in the treatment of certain cancers. (Nguyen and Hojjati 2011).

Infection and arthritis.

Reactive arthritis - Lyme - Whipple - HIV - Viral arthritis - Septic arthritis

Ashish J Mathew, Debashish Danda, Hill Gaston

A previous version was coauthored by Maxime Breban, Riita Koivuniemi, Marjatta Leirisalo-Repo, Ben A. Dijkmans, Kari K. Eklund and Janneke Tekstra.

LEARNING OUTCOMES

- Distinguish between infectious arthritis and inflammatory arthritis
- Diagnose and treat reactive arthritis
- Treat infectious (septic) arthritis
- Diagnose and treat viral arthritides
- Diagnose and treat tuberculosis and leprosy related rheumatic diseases
- Diagnose and treat musculoskeletal symptoms during HIV infection
- Consider the role of infections in the propagation of chronic rheumatic diseases

1 Introduction

The complex association between microbes and autoimmunity has intrigued researchers for centuries. Pyogenic bacteria and viruses can be either causative or precipitating agents for acute infective arthritis, while chronic arthritis is generally caused by mycobacteria, fungi and parasites. Translational research over the past few years has bridged gaps in understanding the immuno-pathogenesis of infective arthritis to a large extent. This chapter gives a comprehensive view of various infection related arthritis.

The relationship between joints and infection can be categorised into two groups:

Group 1 : Septic or infectious arthritis – the causative agent is present within the affected joint and can usually be identified by culture or molecular techniques. It has usually reached the joint from a focus of infection elsewhere in the body;

Group 2 : Post-infectious arthritis – bacterial antigens can be detected in the joint. This includes: Reactive arthritis – infection usually originates in the urogenital or gastrointestinal system and can cause an inflammatory joint disease with features of spondyloarthritis.

2 Bacterial infections and acute arthritis

2.1 Septic arthritis

Septic arthritis refers to the articular manifestations due to the presence of bacteria or fungi within a joint. This is a medical emergency, causing rapid joint destruction if not recognised and treated early. In the majority of cases, the causative organism is a bacterium—the most common aetiological agent being *Staphylococcus aureus*. Infections due to fungi are much rarer. Most articular infections develop as a result of haematogenous seeding of the vascular synovial membrane after a bacteraemic episode. In children, usually there is a breach in the outer cortex of the bone, leading to seeding of bacteria into the intracapsular region. Bacterial arthritis may also arise secondary to penetrating cutaneous trauma, following, for instance, a plant-thorn wound or an animal bite. Bacteremia from gastrointestinal and genito-urinary tracts result in Gram negative septic arthritis. Very rarely, septic arthritis occurs as a result of local glucocorticoid joint injection, other intra-articular procedures or joint replacement surgeries.

Pyogenic bacterial arthritis typically presents as an acute, very painful monoarthritis with fever. Irreversible loss of joint function develops in 25–50% of patients, mainly related to delayed diagnosis and treatment. It can be a life-threatening condition and mortality has been reported to be as high as 10%. This mortality rate increases, with estimates as high as 50%, when sepsis involves several joints.

Septic (purulent) arthritis is usually divided into two entities: (a) non-gonococcal arthritis and (b) gonococcal arthritis. The division is useful in clinical practice because the risk factors, clinical features and treatment differ greatly between the groups (table 1).

Table 1 Non-gonococcal and gonococcal arthritis—predisposing factors, clinical and laboratory features

Clinical feature	Non-gonococcal	Gonococcal
Age	Risk increases with age	Sexually active young adults
Gender	No difference	4 times more common in females
Menstruation	No increased risk	Increases risk
Complement deficiency, systemic lupus erythematosus	Risk for <i>Neisseria meningitidis</i> infection	Risk for <i>Neisseria gonorrhoeae</i> infection
Presentation	Single joint involvement	Migratory polyarthritis
Tenosynovitis	Uncommon	Common
Polyarthralgia	Uncommon	Common
Pustular dermatitis	Absent	Does occur
Culture positivity	Nearly 90%	Less than 50%
Prognosis	Bad	Good

2.1.1 Non-gonococcal arthritis

2.1.1.1 Incidence

The incidence of acute joint infection (septic arthritis) is 5–9 per 100 000 person-years (Margaretten et al, 2007). A high suspicion of septic arthritis is pivotal, considering the swift damage it causes if not detected early and treated aggressively. Patients with advanced age, rheumatoid arthritis (RA) and those who are immunocompromised or have abnormal joint structure or a joint prosthesis are at increased risk for joint infection (box 1).

2.1.1.2 Clinical symptoms and diagnosis

In about half of the adult patients with septic arthritis, the infection occurs in abnormal joints. Usually the patient presents with an acutely swollen joint, often a large joint such as the knee or ankle. The joint is usually swollen, warm, can be even erythematous, tender on palpation and often very painful on movement (figure 1). The clinical presentation may vary according to the virulence of the causative organisms, which is low for mycobacterial and fungal infections. –In the case of pre-existing arthritis, the affected joint often shows signs that are out of proportion to disease activity detected in other joints.

Box 1 Risk factors for the development of septic arthritis

Systemic features

- Degenerative joint disease
- Immunosuppressive condition
 - o AIDS
 - o Chronic renal failure
 - o Organ transplantation
 - o Hypogammaglobulinaemia
- Diabetes mellitus
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Immunosuppressive therapy including some biologics

Local factors

- Trauma penetrating into the joint
- Prosthetic joints
- Open reduction of fractures
- Intra-articular procedures

Social factors

- Low socioeconomic status
- Occupational exposure to animals
- Alcoholism and chronic liver disease
- Intravenous drug abuse

Others

- Extremes of age

Figure 1 A 70-year-old man with fever and swollen right ankle for 1 week. Note septic skin lesions on the leg. Synovial fluid and blood cultures positive for *Staphylococcus aureus*.

Infection in more than one joint occurs in about 20% of patients, mostly with underlying chronic diseases, an immunosuppressive state or drug abuse. About 50% of patients have high fever, while sweats and rigors occur only in about a quarter. In patients with RA using glucocorticoid, immunosuppressive or biological treatments, the joint pain and symptoms of acute infection may be masked, which can lead to a delay in diagnosis.

The differential diagnosis of acute monoarthritis is presented in box 2.

Box 2 Differential diagnoses for acute monoarthritis

- Septic arthritis
- Crystal arthritides
 - o Gout
 - o Pseudogout
 - o Apatite-related arthropathy
- First symptom/presentation of inflammatory diseases such as rheumatoid arthritis
- Reactive arthritis
- Lyme arthritis
- Transient synovitis of the hip
- Pigmented villonodular synovitis
- Haemarthrosis
- Neuropathic arthropathy
- Osteoarthritis
- Intra-articular injury (fracture, meniscal tear, osteonecrosis)
- Metastatic carcinoma

The prevalence of septic arthritis in hospital series of patients with monoarthritis is 8–27%.

If septic arthritis is suspected, arthrocentesis of the joint is mandatory, and the synovial fluid is analysed for Gram stain, white blood cell (WBC) count and differential, and cultured for bacteria. Staphylococci or streptococci cover about 90% of the infections. Gram-negative organisms are more common in older patients and in those who are immunocompromised (table 2). The sensitivity of Gram staining and bacterial cultures of the synovial fluid to detect the infection is, however, limited. The Gram stain is positive in 71% of Gram-positive septic arthritis, 40–50% of cases of Gram-negative septic arthritis, and in <25% of cases of gonococcal septic arthritis (see below) (Garcia-De La Torre and Nava-Zavala, 2009*). Microscopy is positive in only 50% of cases (Mathews et al, 2007). A synovial fluid WBC count of > 50000/cu mm and > 100000/cu mm has been shown to have a positive likelihood ratio of 4.7 (95% CI 2.5 – 8.5) and 13.2 (95% CI 3.6 – 51.1) respectively for septic arthritis in a meta-analysis. (Carpenter et al, 2011). The presentation of septic arthritis may be mimicked by a pseudo-septic pattern in the setting of calcium pyrophosphate deposition disease as the latter can present with fever, turbid, purulent looking synovial fluid, with neutrophilic leukocytosis of > 50000 / cu mm. PCR of the synovial fluid does not offer any advantage compared with microscopy and culture. Laboratory markers of

systemic inflammation (increased WBC count, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)) have only a limited diagnostic value owing to their low sensitivity. A markedly raised serum CRP (>100 mg/L) increases the likelihood of septic arthritis only slightly by a likelihood ratio of 1.6. Serum procalcitonin has been shown to be a sensitive marker to differentiate septic and non-septic arthritis in the early stages. However, its role in guiding antibiotic therapy needs to be elucidated further. Procalcitonin cut-off for infections with generalized sepsis is generally accepted to be 0.5 ng/ml, while a lower cut-off may have to be used for localized infections. However, caution should be exercised in interpreting the results as diseases like adult onset Still's disease and ANCA associated vasculitis can also have elevated procalcitonin levels. (Shaikh MM et al, 2014). The concentration of WBCs in the synovial fluid is usually increased, and a count of $>50 \times 10^9/L$ with >90% of polymorphonuclear cells increases the likelihood of septic arthritis. Evidence of infection should also be searched for outside the joint (chest X-ray examination, cultures of urine, blood, throat, wounds, skin blisters, etc.) (figure 2).

Table 2 Pre-existing morbidities and their association with infective organisms in septic arthritis

Underlying disorder	Possible infection
Rheumatoid arthritis	<i>Staphylococcus aureus</i>
Osteoarthritis	<i>Staphylococcus aureus</i>
Alcoholism	<i>Klebsiella pneumoniae</i>
Malignancy	Gram-negative bacteria
Use of immunosuppressive drugs	Gram-negative bacteria
Intravenous drug abuse	<i>Pseudomonas aeruginosa</i> , <i>Staphylococcus aureus</i>
Systemic lupus erythematosus	<i>Salmonella</i> , <i>Neisseria meningitidis</i> , <i>Streptococcus pneumoniae</i>
Complement deficiency	Encapsulated microbes
HIV	No major difference from non-HIV patients

Figure 2 The same patient as in figure 1. Septic lesion on right knee.

Radiography of the joint is usually normal, unless there is a pre-existing chronic rheumatic condition such as RA or osteoarthritis; however, radiographic features of underlying chondrocalcinosis and osteomyelitis should be sought, but note that the former can co-exist with septic arthritis. In established septic arthritis radiographs may reveal juxta-articular osteoporosis, diffuse joint space narrowing due to cartilage destruction and erosions in areas of reflection of the synovium onto the bone (figure 3). At a late stage the joint may appear badly destroyed. Musculoskeletal ultrasound may show non-echo-free effusions, characteristic of septic arthritis. Magnetic resonance imaging (MRI) has greater resolution for soft-tissue abnormalities and aids in early diagnosis of septic arthritis.

Figure 3 Septic arthritis of the right hip due to non-typhi salmonella in a 64-year-old-man.

An X-ray examination shows severe joint space loss, demineralisation and geodes in the femoral head and acetabula roof. Despite appropriate antibiotic therapy, the post-treatment course of the patient in figure 3 was not favourable and surgery was therefore undertaken to remove the right femoral head. Antibiotics were continued and a total hip prosthesis was implanted 3 months later.

2.1.1.3 Treatment

A high suspicion of septic arthritis should prompt treatment with parenteral antibiotics without waiting for the results of bacterial cultures, and drainage of the infected joint, which are the cornerstones of treatment. The

decision about treatment can be guided by microscopy and routine analysis of synovial fluid, but a negative Gram stain does not exclude septic arthritis. The choice of antibiotic is primarily empirical and based on the likelihood of the organism involved and comorbidities (table 3). When the culture results are available, antibiotics can then be chosen according to the sensitivity pattern. The duration of the intravenous treatment should be 10–14 days, often followed by oral antibiotics. The total duration of treatment, usually 6 weeks, depends on the infecting microorganism, other concomitant diagnoses and treatment options, as well as the initial response to the treatment.

Table 3 Antibiotic treatment of septic arthritis. (Modified from Mathews et al, *Ann Rheum Dis* 2007;66:440–5; Mathews and Coakley, *Curr Opin Rheumatol* 2008;20:457–62)

Patient group	Antibiotic choice
No risk factors for atypical organism	Staphylococcal penicillin (eg, cloxacillin or Flucloxacillin) 2 g four times a day IV Fusidic acid 500 mg three times a day by mouth, or gentamicin IV may be added In the case of penicillin allergy, clindamycin 450–600 mg four times a day, or second- or third-generation cephalosporin
High risk of Gram-negative sepsis	Second- or third-generation cephalosporin (eg, cefuroxime 1.5 g three times a day)
MRSA (methicillin-resistant <i>Staphylococcus aureus</i>) risk	Vancomycin 1 g two times a day IV plus second- or third-generation cephalosporin
Suspected gonococcus or meningococcus	Ceftriaxone 1 g once a day (IM or IV) or similar drugs, depending on local policy/resistance
Intravenous drug users	Consult local microbiologist
Patients in the intensive therapy unit, known colonisation of other organs	Consult local microbiologist

Drainage of the inflammatory debris is mandatory for preserving joint function and limiting joint destruction. This can be performed as daily needle aspiration, arthroscopic debridement with lavage, open lavage or arthrotomy with synovectomy. No randomised studies have shown superiority of any of these interventions (Mathews and Coakley, 2008). In practice, if a joint is easily accessible by needle arthrocentesis, this approach can be used. In a complicated case or for a joint with limited access (eg, hip and shoulder joints), arthroscopic or open lavage would probably have a better therapeutic effect. In addition to the above-mentioned treatment options, non-steroidal anti-inflammatory drugs (NSAIDs) or analgesics should be prescribed according to the patient's symptoms. Unloading of the affected joint is recommended until infection is controlled. Physiotherapy to prevent muscular atrophy and contractures should be instituted early, first as manual mobilisation of the joint and isometric contraction of the quadriceps muscle in the case of knee infection. Partial weight bearing can be started later on, with more active mobilisation only when inflammation is suppressed.

2.1.1.4 Outcome

The outcome of septic arthritis varies and seems to depend on the duration of symptoms, type of organism, type of joint drainage, pre-existing joint problems and coexisting osteomyelitis. The functional outcome depends on the presence of degenerative changes in the joint before infection and on the patient's age (figures 4A and B).

Figure 4 (Top) X-ray picture of the ankle of the patient in figure 1 at entry. Notice the destructive lesions in the ankle. (Bottom) X-ray picture of the right ankle 1 year later. Notice the total destruction of talocrural arthritis with periosteal reaction.

2.1.1.5 Rare bacterial infections

More subacute or chronic forms of infectious arthritis with insidious onset and considerable delay in diagnosis may be caused by mycobacteria and brucella species. Clinical suspicion is based on knowledge of host susceptibility, endemic areas of specific organisms and the usual clinical patterns of musculoskeletal involvement.

Mycobacterium tuberculosis arthritis Musculoskeletal manifestations of extra-pulmonary tuberculosis have been described in 10-15% of patients. (Malaviya et al, 2003). The prevalence varies widely with geographical location. -There are many ways in which Mycobacteria can affect the joints –

- a) Direct invasion – septic arthritis
- b) Secondary infection of joints, following inflammatory or degenerative changes
- c) Following intra-articular procedures such as corticosteroid injections or arthroscopies, or in prosthetic joints
- d) Reactive arthritis – Poncet's disease

Musculoskeletal involvement is caused by haematogenous and/or lymphatic spread of tuberculosis bacilli from other lesions, such as a quiescent pulmonary primary localisation or another extraosseous focus. Usually the patient presents with a slow onset monoarthritis of a weightbearing joint (eg, hip, knee), with only mild or no systemic symptoms. In the early stage of the disease, tuberculous arthritis may easily be mistaken for a degenerative condition. The significant delay between the onset of symptoms and definitive diagnosis commonly ranges between 5 and 50 months. The prevalence of prosthetic joint tuberculosis has been steadily rising in endemic areas. Advanced age (>70 years), tuberculosis in the past, and chronic immunosuppression therapy are risk factors for tuberculosis of prosthetic joints. (Kim et al, 2013). Systemic symptoms, frequently absent at the beginning of the joint involvement, may include a low-grade fever, asthenia, decreased appetite, weight loss and night chills. Chest radiographs can be normal. Radiographs of affected joints can show diffuse joint space narrowing and bony erosions. The Phemister's triad of periarticular osteoporosis, peripherally located osseous erosion and gradual reduction of intraosseous space is highly specific for tuberculous arthritis. MRI can clearly determine severity and extent of joint damage. MRI features of rheumatoid arthritis can also mimic those of tuberculous arthritis. Uneven and extensive synovial thickening is pathognomonic of rheumatoid arthritis, whereas, larger bone erosions with rim enhancement and extra-articular cystic mass are more common in tuberculous arthritis. (Choi et al, 2009). Confirmatory diagnosis depends on the isolation of *Mycobacterium tuberculosis*. Ziehl–Nielssen staining of synovial fluid is only positive in 10–20% of cases. Cultures of synovial fluid and synovial tissue are positive in 80% and 94% of cases, respectively, and PCR is being used increasingly to make a more rapid diagnosis. Synovial biopsy is of major interest for articular tuberculosis infection, since

histology can show the chronic caseating granulomatous inflammation long before bacterial cultures become positive.

Poncet's disease, a non-suppurative reactive arthritis (see below), mainly occurs in patients with extrapulmonary tuberculosis. Erythema nodosum is a characteristic feature in these cases. Patients present with asymmetric, oligo-polyarthritis, mostly involving large joints of lower limbs, and sparing the axial skeleton. Arthritis resolves within weeks of initiating anti-tuberculous therapy, and generally there is no tendency for progression to chronic arthritis. (Rueda et al, 2013).

Atypical mycobacterial infection Clinical manifestations of atypical mycobacterial infection resemble those of tuberculosis, but tenosynovitis, bursitis, periarticular discharging sinus and polyarthritis are more common. Non-tuberculous mycobacteria include *Mycobacterium avium*, *Mycobacterium marinum*, *Mycobacterium kansasii*, *Mycobacterium abscessus* and *Mycobacterium chelonae*. The most commonly affected joints are knees, hands and wrists, which are usually infected through direct inoculation. Infection with *Mycobacterium marinum* frequently involves the hands or wrists, most often in association with a history of periarticular trauma or exposure to marine environments. Intra-articular injections are a common route of entry for these organisms. Patients with atypical mycobacterial infection are mostly immunocompromised (e.g., diabetes mellitus, end-stage renal disease, haemodialysis patients, HIV infection).

***Mycobacterium leprae* infection** The prevalence of arthritis in leprosy varies widely, depending on the geographical location, with high rates being reported from countries in Asia and Central America. Patients with lepromatous leprosy have been shown to have a higher prevalence of arthritis. An explosive onset, acute symmetric polyarthritis, involving small joints of hands and feet, and associated with the Lepra reaction is the commonest presentation. Symptoms last for a few weeks and resolve with treatment. Patients can also present with tenosynovitis alone (swollen hands and feet syndrome). Demonstration of acid-fast bacilli in joints is the gold standard for diagnosis. Plain radiographs of extremities reveal periosteal reaction, subarticular cysts, acro-osteolysis, subluxation or complete destruction of joints. The presence of rheumatological manifestations warrants addition of immunosuppression along with multi-drug therapy. (Gupta et al, 2016; Danda D et al, 2001)

Brucellosis This infection is often acquired by ingestion of contaminated milk or dairy products, and manifests as a febrile illness with hepatosplenomegaly, lymphadenopathy and leucopenia or pancytopenia. *Brucella mellitensis* is most often the causative agent, but disease due to *Brucella abortus* and *Brucella suis* also occurs. History of ingestion of infected unpasteurised dairy products or professional exposure is an important clue to the diagnosis, especially in combination with travel to endemic countries. Besides these manifestations, musculoskeletal lesions are present in one-third of patients. Common osteoarticular manifestations of brucellosis are acute unilateral sacroiliitis, or peripheral arthritis involving predominantly the large joints of lower limbs. If brucella infection is suspected, the laboratory should be consulted since this organism requires a

special culture medium and extended culture time for its growth in culture. Even when cultured in special medium, only 50% of synovial fluid cultures are positive. PCR is useful for detection of brucella DNA in synovial fluid or tissue. In the absence of bacteriological confirmation, positive brucella serology (titre >1:160, or a significant rise in brucella antibody titre) might help the diagnosis. However, cross-reactivity in serological testing between brucella and *Yersinia enterocolitica* and salmonellae must be taken into account. Only culture allows differentiation of the different brucella species.

2.1.1.6 Fungal arthritis

The onset of fungal arthritis is usually insidious. Articular infections become symptomatic weeks after an episode of fungaemia and clinical symptoms are often more subtle than in bacterial infections, leading to long delays in diagnosis. Primary fungal infections of lung and skin are common, but dissemination to other organs occurs predominantly in patients with a suppressed immune status or receiving prolonged intravenous antibiotics. Clinical clues include trauma with possible inoculation, travel to endemic areas, failure to identify a causative pathogen on synovial fluid cultures, failure to respond to antibiotic therapy or immunodeficiency.

Especially at risk for invasive candida or aspergillus infections are patients with neutropenia receiving glucocorticoid therapy, with central venous catheters, receiving broad-spectrum antibiotics, with a history of, or current detection of, candidaemia, and intravenous drug abusers. Diagnosis is established by detection of the fungus in synovial fluid or bone tissue, either by direct (histological) techniques or culture.

2.1.2 Gonococcal arthritis

In 0.5–3% of gonorrhoea infection, the pathogen can gain access to the bloodstream from the primary mucosal site of infection and produce disseminated gonococcal infection (DGI). Gonococcal arthritis occurs in about 42–85% of such patients. DGI manifests itself in two major forms, with extensive overlap between them. The disseminated form causes tenosynovitis, dermatitis and fever. The patient may also have myopericarditis, meningitis and full-blown sepsis. The septic arthritis form causes monoarthritis or polyarthritis and fever. Dermatitis is less common than in the bacteraemic form.

2.1.2.1 Occurrence

Gonococcal infection used to be the leading cause of septic arthritis among young adults, but the disease has become rare in Western countries after the introduction of effective control programmes. The incidence is lower in Europe than in North America. In Europe, about 1% of septic arthritis is caused by gonococci (Bardin, 2003). In the USA, gonococcal arthritis is mainly seen in urban ethnic minorities with low socioeconomic status. In Africa, the disease is still prevalent. Gonococcal arthritis is three to four times more common in women than in men. This is probably due to asymptomatic local infection, which is more common in women, and allows spreading of the infection. Other risk factors for gonococcal arthritis are pregnancy, menstruation, multiple

sexual partners, male homosexuality, low socioeconomic status, intravenous drug use, complement deficiency, HIV infection and systemic lupus erythematosus.

2.1.2.2 Clinical symptoms and diagnosis

Patients with the disseminated form often have severe polyarthralgia (but a severe polyarthritis is uncommon), fever and chills. Skin lesions (non-pruritic, tiny papules, pustules or vesicles with an erythematous base) in the trunk or extremities occur in >50% of patients (figure 5). Tenosynovitis occurs also in >50% of patients. Predilection is for the dorsum of hands, fingers and feet, wrist and ankles. The septic form is less common. A purulent monoarthritis or oligoarthritis is the major feature. Joint fluid cultures may be positive, but blood cultures are not.

Figure 5 Gonococcal pustules in a patient with disseminated gonococcal infection. (Courtesy of Seattle STD/HIV Prevention Training Centre, University of Washington, WA, USA. Source: Negusse Ocbamichael.)

The diagnosis is based on the clinical picture of DGI supplemented with evidence of gonococcal infection. Gonococcal cultures of the urethra/cervix, rectum and oropharynx should be performed and are positive in about 80% of cases. Blood culture is positive in <50% of patients. Joint aspiration is positive in about 50% of the cases; bacterial cultures of the skin lesions are usually negative. Contact tracing and cultures from partners can help in the diagnosis (Bardin, 2003).

Patients with gonococcal arthritis can have raised WBC in the blood, as well as raised ESR and CRP. Synovial fluid shows an inflammatory pattern. Ligase chain reaction and polymerase chain reaction (PCR) are available for the detection of nucleic acid sequences specific for *N. gonorrhoea* in urogenital samples, first-void urine, prostatic

massage fluid or synovial samples. Cultures are preferred because the microbial sensitivity pattern can also be determined. Serological tests perform less well.

2.1.2.3 Treatment

Initial treatment (depending on local resistance) is a third-generation cephalosporin, e.g. ceftriaxone 1 g once a day (table 3). If the microbe is sensitive to penicillin, the treatment can be switched to G-penicillin 10^6 IU/day intravenously (IV) in divided doses. In cases of penicillin allergy, spectinomycin 2 g IV twice a day can be given. The arthritis responds very quickly to antibiotic treatment. This can be used even as a diagnostic test in a patient with a typical clinical picture and negative cultures. Parenteral antibiotics should be continued for 1–3 days after resolution of the symptoms. Thereafter, oral treatment (cefixime 400 mg twice a day, ciprofloxacin 500 mg twice a day or amoxicillin 500 mg three times a day) can be continued for 7–10 days to complete the treatment. After the treatment, microbial cultures from foci which were positive before antimicrobial therapy should be re-examined. Patients should be screened for other sexually transmitted diseases. A co-infection with *Chlamydia trachomatis* can also be the cause of the arthritis in the patient. Contact tracing and treatment is part of health policy. Other treatment procedures are similar to those described above for non-gonococcal septic arthritis. The joints in the patient with DGI are usually very painful, and need NSAIDs or analgesics. Physiotherapy should be started as in non-gonococcal arthritis.

2.1.2.4 Outcome

The prognosis of both forms of gonococcal arthritis is usually good, provided that antibiotic therapy is started in due time. Sometimes, gonococcal infection appears to be associated with a more prolonged form of sterile arthritis, mimicking reactive arthritis. Usually such an event is associated with a co-infection with *Chlamydia trachomatis*.

2.2 Prosthetic joint infections

The rate of prosthetic joint infections ranges from 0.5% to 1% for hip and knee replacements, the most important risk factor being a revision arthroplasty. Early-onset infections are usually the result of perioperative wound contamination and are most often caused by coagulase-negative staphylococci. Infections that begin later than 3 months after the surgical procedure are more often due to *Staphylococcus aureus*, streptococci or Gram-negative bacilli through haematogenous dissemination.

Clinical features of infections within the first few months of surgery are pain, erythema and drainage at the wound site. By contrast, late-onset infections present with gradually progressive joint pain without fever or other signs of infection. Radiological evidence of joint loosening is often present but does not differentiate mechanical from septic loosening.

If prosthetic joint infection is suspected, synovial fluid must be aspirated for bacterial analysis, under strict aseptic conditions. Treatment usually requires the surgical removal of all the prosthetic components. Rarely, early-onset infections can be eradicated by debridement and a long course of parenteral antibiotics. Patients with late-onset infection will most often require removal of the prosthesis, extensive debridement and a later replacement arthroplasty. Patients at high risk or those refusing replacement arthroplasty are treated with long-term antibiotics.

2.3 Spondylodiscitis

Estimates of its prevalence range from 4 to 24 per million a year in developed countries. Most often pathogens infect the spine by haematogenous spread, rarely through direct inoculation or spread from contiguous tissues. Overall, the pathogens responsible for spondylodiscitis are the same as those for septic arthritis (bacteria in the majority of cases, namely *Staphylococcus aureus*, streptococci, enterobacteriaceae, etc.), but the prevalence of tuberculosis is also high, accounting for 10–40% of spondylodiscitis. Infections due to fungi are rare. Pyogenic spondylodiscitis affects preferentially the lumbar spine, followed by the thoracic and cervical spine. In contrast, tuberculosis most often affects the thoracic spine, and more often involves several vertebral bodies. Clinical features of pyogenic spondylodiscitis include moderate to severe back pain progressing over a short period of time, which is typically present or worse at night, and sometimes associated with fever. Patients with tuberculosis spondylodiscitis usually present with slow-onset back pain with weight loss, aesthenia and night sweats. In both the scenarios, neurological symptoms may be present, depending on extension of the infectious process into the spinal cord or spinal nerve roots.

On clinical examination, a marked stiffness of the spine in the frontal and sagittal planes is usual. Imaging features of spondylodiscitis are subchondral radiolucency, erosions and loss of definition of the endplate and loss of disc height. A paravertebral soft tissue mass, particularly within the psoas muscle, is frequently seen with tuberculous spondylodiscitis. MRI is the preferred choice for radiological diagnosis of spondylodiscitis because it provides anatomical information particularly relating to the epidural space and spinal cord. The characteristic changes consist of decreased signal intensity from disc and adjacent vertebral bodies on T1-weighted images with gadolinium enhancement, and increased signal intensity on T2-weighted images. Presence of large paraspinal abscesses is highly suggestive of tuberculosis infection (figure 6). Microbiological investigations include blood cultures and above all a percutaneous biopsy for culture and histology of the infected disc or vertebral body. The principles of treatment for septic spondylodiscitis are identical to those for septic arthritis i.e, appropriate antibiotic therapy, initially parenterally (except for tuberculosis) and then orally, for a total duration of 8–12 weeks. The treatment regimen for tuberculosis is isoniazid and rifampicin, with pyrazinamide and ethambutol for the first 2 months, followed by isoniazid and rifampicin for a total duration of 10–12 months. Whatever the pathogen, bed rest for about 2 weeks is important to prevent spinal deformity, which should be

followed by immobilisation in a corset. Search for a portal entry is of course mandatory. Indication for surgical intervention is mainly based on the presence of compression of neural elements.

Figure 6 Tuberculous spondylodiscitis in a 28-year-old man. X-Ray and MRI of the spine (T1-weighted images). Collapse of a vertebral body with marked erosive changes involving anterior and inferior portion of adjacent bodies. MRI shows discitis associated with epiduritis and soft tissue masses.

2.4 Reactive arthritis (ReA)

Classical ReA belongs to the family of spondyloarthritides, which share features such as inflammatory low back pain, oligoarthritis and extra-articular symptoms. There is no universal agreement on the classification and diagnostic criteria for reactive arthritis. The disease was originally defined as arthritis developing soon after, or during an infection elsewhere in the body, without microorganism entering the joint as viable bacteria. Though the presence of microbial antigenic material, even replicating microbes, has been demonstrated in the joints of some patients with typical ReA microbial cultures are negative. The term 'Reiter's syndrome', an old synonym for ReA, was removed for historical reasons. In 1999, the 4th International Workshop on ReA discussed the use of the term ReA and proposed that it should be used only if the clinical picture and the microbes involved are associated with HLA-B27 and spondyloarthritis, whereas the term 'infection-related arthritis' is used for all other

arthritis related to, or associated with, infections (Braun et al, 2000). Preliminary classification criteria were proposed by the workshop (box 3). These criteria can be used in decision-making, although their use in clinical practice is limited by practical problems in acquiring synovial tissue samples for immunohistology and PCR.

Box 3 Preliminary classification criteria for reactive arthritis

Major criteria

1. Arthritis, with two of three of the following findings
 - Asymmetric
 - Monoarthritis or oligoarthritis
 - Affecting predominantly the lower limbs
2. Preceding symptomatic infection, with one or two of the following findings
 - Enteritis (diarrhoea for at least 1 day, 3 days to 6 weeks before the onset of arthritis)
 - Urethritis (dysuria or discharge for at least 1 day, 3 days to 6 weeks before the onset of arthritis)

Minor criteria, at least one of the following

1. Evidence of triggering infection
 - Positive urine ligase reaction or urethral/cervical swab for *Chlamydia trachomatis*
 - Positive stool culture for enteric pathogens associated with reactive arthritis
2. Evidence of persistent synovial infection (positive immunohistology or PCR for *Chlamydia*)

Exclusion criteria

- Other causes for acute arthritis

Definition of reactive arthritis

- Definite reactive arthritis: both major criteria and a relevant minor criterion
- Probable reactive arthritis: both major criteria, but no relevant minor criteria

or

- Major criteria 1 and one or more of the minor criteria

Modified from Braun et al, *J Rheumatol* 2000;**27**:2185–92.

2.4.1 Triggering infections

Microbes associated with reactive arthritis are usually Gram-negative bacteria, mostly facultative or obligatory intracellular organisms. The primary focus of infection is through the mucosal membrane, usually in the gut or in the urogenital tract (box 4).

Box 4 Microbial infections associated with the development of reactive arthritis**Enteric bacteria**

- *Salmonella** (various serovars)
 - *S. typhimurium*
 - *S. enteritidis*
- *Shigella**
 - *S. flexneri*
 - *S. dysenteriae*
 - *S. sonnei*
- *Yersinia**
 - *Y. enterocolitica* (especially O:3 and O:9)
 - *Y. pseudotuberculosis*
- *Campylobacter**
 - *C. jejuni*
 - *C. coli*
 - *C. lari*
 - *C. fetus*
- *Clostridium difficile* *
- *Giardia lamblia*
- *Escherichia coli* O157

Bacteria causing urethritis

- *Chlamydia trachomatis* *
- *Mycoplasma genitalium* #
- *Ureaplasma urealyticum* #
- *E. coli*

Bacteria causing respiratory infection

- *Chlamydia pneumoniae*
- *Campylobacter pneumonia*

* HLA B27 associated. #Cause urethritis, but the role in reactive arthritis still being discussed

The classic microbes in the gastrointestinal tract causing ReA include yersinia, salmonella, shigella and Campylobacter jejuni. Originally, Shigella flexneri was the only shigella species known to be associated with reactive arthritis, but according to a large epidemiological survey, all species of shigella can trigger reactive arthritis (Hannu et al, 2006*). Other less frequently diagnosed infections in association with reactive arthritis include Campylobacter lari, Chlamydia psittacii and Clostridium difficile. Chlamydia pneumoniae, a respiratory pathogen, may be involved in about 10% of patients with reactive arthritis. Bacteria belonging to the normal gut flora (such as Escherichia coli) have only occasionally been connected with reactive arthritis. However, enteritis caused by enterotoxigenic E. coli O157 has been increasingly implicated with the development of reactive arthritis (Townes et al, 2008; Rohekar and Pope, 2009).

Chlamydia trachomatis is by far the most common cause of genital infection and also the most common triggering infection for reactive arthritis. Of the other microbes causing urethritis, *Neisseria gonorrhoea* probably does not trigger true reactive arthritis, though the infection is well known to cause bacteraemic and septic arthritis (see above). Infection with *Mycoplasma genitalium* and *Ureaplasma urealyticum* is connected with urethritis, but their role as an independent trigger for ReA (in the absence of chlamydia infection) is still discussed.

2.4.2 Epidemiology of reactive arthritis

The annual incidence of reactive arthritis varies from country to country, but in epidemiological studies, it has been reported as 1–30/100 000, *Chlamydia trachomatis* and enterobacteriaceae playing an equal aetiological role. *Campylobacter* has recently been recognised as one of the most important infections to cause gastroenteritis in the Western world, where shigella infections are uncommon and usually imported from the developing world. (Hannu et al, 2006*; Townes et al, 2008).

2.4.3 Genetic component in reactive arthritis

Genetic factors influencing susceptibility partially explain the reason why only 1–15% of infected subjects develop reactive arthritis. In hospital-based series, about 60–80% of patients have HLA-B27, the presence of which is associated with a more severe arthritis and occurrence of extra-articular features. It also predicts a prolonged disease. In studies of defined outbreaks or in epidemiological surveys at population level, the picture is different. The disease is usually mild, oligoarticular or polyarticular, and there is only a slight or no increased frequency of HLA-B27 (Leirisalo-Repo, 2005a).

2.4.4 Pathogenesis of reactive arthritis

The classic bacteria capable of triggering reactive arthritis are Gram-negative obligate or facultative intracellular aerobic bacteria with a lipopolysaccharide-containing outer membrane. They are invasive and cause primary infection of gastrointestinal mucosa (enteric pathogens) or urogenital mucosa (*Chlamydia trachomatis*). The invasiveness of the bacteria is probably not contributed to by host genetic factors (HLA-B27), but there is abundance of evidence in favour of the hypothesis of an impaired elimination of the microbes in the infected host. In patients with reactive arthritis, bacterial antigens seem to disseminate in the body, and chlamydia, yersinia, salmonella and shigella antigens have been detected in the synovial fluid or in synovial tissue. Yersinia DNA and RNA as well as chlamydial DNA and RNA have been detected by sensitive techniques in the joints, but also in some asymptomatic control subjects. There is increasing evidence that *Chlamydia trachomatis* can persist in the host for years. Furthermore, recent studies have shown that patients with chronic seronegative oligoarthritis/polyarthritis, with a diagnosis of chronic spondyloarthritis, harbour chlamydia antigens in synovial

tissue and peripheral blood at a higher frequency than in control subjects with osteoarthritis (Carter et al, 2009*).

After invasion via the mucosal route, the microbes persist either in the epithelium or within associated lymphoid tissues, liver and spleen. The viable organisms or bacterial antigens are disseminated to the joint, causing a local inflammatory response. A CD4+ T-cell response to the invading micro-organism is readily detected in the joint and may drive the arthritic process, supported probably also by a CD8+ T cell response. It is possible that the acquired immune response to the organism may be inadequate in ReA, and favour the persistence of the microbes/microbial antigens and contribute to the poor elimination of the antigens in the host (Gaston and Lillicrap, 2003*).

While HLA-B27 is not required for the development of reactive arthritis, its presence contributes to the severity and chronicity of the disease. The role of HLA-B27 in this process has been discussed, and one of the early hypotheses was a cross-reaction between microbial structures and HLA-B27 – “molecular mimicry”, or that HLA-B27 itself might be a target of the immune response. Currently the molecular mimicry hypothesis has not been proven, and not found when specifically sought, but remains a possibility. Alternatively, the persistence of microbial structures in the host might be explained by an impaired elimination of the microbes by deficient cytokine production which might in turn be related to unusual characteristics of HLA-B27. These views assume that the role of HLA-B27 in ReA is similar to its role in ankylosing spondylitis.

2.4.5 Clinical symptoms and diagnosis
